#### ABSTRACT

A direct design method for solving the problem of robustness to cross-ccupling perturbations in multivariable control systems is presented. The method uses numerical optimization procedures to manipulate the system feedback gains as direct design variables. The manipulation is accomplished in a manner that produces desired performance by pole placement and robustness by modification of the minimum singular values of the system return difference matrix.

Channels affected by cross-coupling perturbation may be recognized by the character of their transfer function plot. The mechanism used by the pole placement and robustness routine in obtaining a robust-design is evident from the gain changes associated with the transfer function diagram and the zero shifts shown on pole-zero plots. The pole placement and robustness routine uses gain equalization and zero assignment to modify the characteristics of the system in the areas of low singular values, producing a robust design.

A modification of the pole placement and robustness routine that may be applied to the design of robust observers is also presented. Using feedback and filter gains as direct design variables a practical design procedure for robustness recovery in observer based systems is obtained.

#### ACKNOWLEDGEMENTS

For over fifteen years the United States Navy has allowed me to make practical application of the science of flight as a Naval Flight Officer and as a flight test project officer. I wish to express my appreciation to the Navy and the citizens of the United States for the opportunity to further expand my knowledge of aviation by pursuing this degree.

I would also like to express a sincere thank you to the Doctoral Committee of professors Platzer, Gawain, Latta, Strum and Collins for their support in these efforts. Of course special thanks must go to Professor D.J. Collins for heading the committee and having worked so long and hard with me on two theses. Without his support this effort would never have been completed.

Thanks are also expressed to Professor G.N. Vanderplaats for allowing me to use the Automated Design Synthesis code. His help in integrating the code into the pole placement and robustness design program and the insight into the power of numerical optimization that he provided were extremely beneficial to the outcome of this thesis.

The Naval Postgraduate School Library staff and Roger Martin are appreciated tremendously for providing excellent service. No request for reference material was ever too difficult for them to handle. The W.R. Church Computer Center is acknowledged for their support in the computational processing for this thesis. I would also like to acknowledge the work of CDR Al Diel and LTs Cliff Cooksey, John Hoden and Mike Laptas for the work done to provide an excellent control system analysis package at the Naval Postgraduate School. Their efforts made the analysis of data from the pole placement and robustness routine much easier.

I would also like to thank my wife, Janice, and children, Bradley and Melissa. As anyone knows who has undertaken an effort of this magnitude without their love and support this would have been impossible. They have "gone it alone" quite often so that this paper could be completed.

Above all thanks to Him who started it all.

#### I. INTRODUCTION

with the rising interest in multivariable control theory brought on by increasingly complex systems the need has arisen to develop design methods that will allow the designer to specify system performance while at the same time ensuring relatively high stability margins or robustness. In the single-input single-output (SISO) case the designer has had the tools to do these tradeoffs in the form of Nyquist, Bode and root locus plots. In the multi-input multi-output (MIMO) case the classical methods are not totally appropriate.

With the increased interest in MIMO systems numerous methods of design have been employed to obtain suitable system performance and robustness with varying degrees of success. One primary method of design is to keep the plant as decoupled as possible throughout the design so that each individual element may be controlled independently designed essentially as a single loop system. Rosenbrock [Ref. 1] has developed a procedure where the multilcop system is modified into system that has a elements that are much larger than any off-diagonal elements. This diagonally dominant system is then in a form where conventional Nyquist type techniques can be employed in the analysis. A third common MIMO design method is that of the linear Quadratic (LC) method. This method uses a quadratic cost functional and optimization principles to allow the designer to design for various performance levels ky adjusting the matrix weighting terms used in the cost The major difficulty with all of the function. methods is that they are not necessarily robust. especially true for cross-coupling terms between loops.

The primary achievement of this thesis has been the incorporation of the time domain pole placement design procedure with a method of using return difference matrix singular values to improve the robustness of the design. The technique, which utilizes a modern optimization routine, can significantly assist the designer in obtaining robustness in the face of cross-courling perturbations. It has also been shown that the cross-coupling perturbation problem can be detected by using classical open-loop Bode diagrams as well as modern control analysis. The pole placement and robustness design routine developed for this thesis has been used on several problems discussed in recent literature. In these studies the pole placement and robustness design code has proven capable of meeting the desired goals of pole placement and robustness and also brought to light some interesting aspects of the cross-coupling perturbation problem. A slightly modified pole placement and robustness routine has proven effective in the design of robust cbservers.

The remainder of the thesis will present background material on SISO systems in Chapter Two and on MIMO systems in Chapter Three. Optimization will be discussed in Chapter Four along with a discussion of the Automated Design Synthesis (ADS) program used as the optimizer routine for the pole placement and robustness design procedure developed in this thesis. The thesis methodology will be discussed and outlined in Chapter Five. This will be followed by chapters discussing results from selected problems. Conclusions will be presented in the final chapter.

#### II. SINGLE-INPUT SINGLE-OUTPUT SYSTEMS

The purpose of this thesis research has been to develop a method of obtaining a robust multivariable control system design. A brief review of the concept of robustness and stability in the framework of a conventional SISO system will be done before pursuing the concepts in a more complicated fashion in the following chapters. A simple interpretation of robustness is the ability of the system to tolerate design perturbations. These perturbations could be in the form of actuator failures, plant parameter uncertainty, unmodeled dynamics or nonlinear terms, or any one of many other perturbations to the nominal design of the system.

The primary reason for feedback systems is the control of uncertainty within the system. By appropriate use of feedback, properties that would lead to an unstable system may be controlled. When stability and robustness aspects are considered for a SISO system, frequency domain design concepts, using either Nyquist or Bode plots, are normally used. Robustness in SISO systems is formulated naturally by the concept of gain and phase margins, both of which are readily available on the Nyquist or Bode diagram.

In figure 2.1 a nominal feedback system can be seen with a perturbation element  $\propto$  (s) placed in series with the nominal system. When  $\alpha=1$  the system is nominal and stable. To determine the positive phase margin of the system the value of  $\alpha$  (s) =  $\alpha$  (j $\alpha$ ) =  $\alpha$  will be changed by varying  $\alpha$ 0 until the system just becomes unstable. This value of  $\alpha$ 1 will then be the system phase margin. The negative phase margin can be computed in the same way. To find the gain margin the magnitude value of  $\alpha$ 1 is increased until the system just

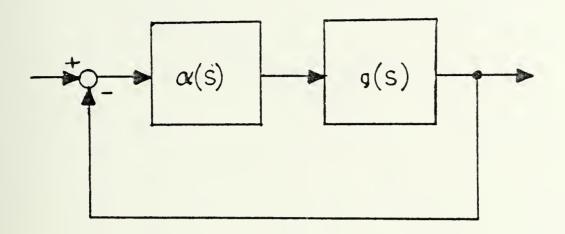

Figure 2.1 Basic Gain and Phase Margin Determination Model.

becomes unstable. This is the upward gain margin. A similar lower margin is also defined.

These gain and phase margins may not be adequate measures of robustness [Ref. 2] because they do not account for simultaneous variation in both gain and phase. Therefore, while large individual gain or phase changes may not destabilize the system, small simultaneous changes in gain and phase may destabilize the system. This is not a major difficulty in classical SISO techniques because the effect can be easily detected.

Gain and phase margin can be defined in terms of the cpen-lcop frequency domain plots in either the Bode or Nyquist format. Figure 2.2 depicts a classical Bode plot showing gain and phase margin determination from the plot. The Nyquist plot may also be used to obtain this information. Nyquist criterion states that if the cpen-loop transfer function G(s)H(s) has n poles in the right half plane and the limit cf G(s)H(s)=constant as  $s \to \infty$  then for a

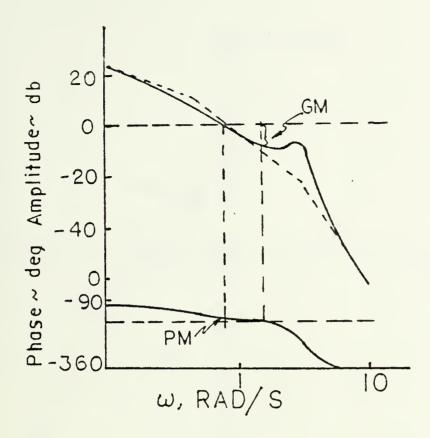

Figure 2.2 Classical Bode Plot.

stable system the locus of G(s)H(s) will encircle the -1+j0 point n times in the counterclockwise direction as s varies along the Nyquist contour. If there are no poles in the right half s plane then the locus will not encircle the -1 + j0 point. The diagram in figure 2.3 illustrates a nominally stable system. The gain and phase margin may be determined directly from the diagram.

Any change in the loop transfer function, provided the order of G(s)H(s) does not change, that changes the number of times the locus of G(s)H(s) encircles the (-1,0) point in the Nyquist plot causes the system to become unstable. This leads to the conclusion that the minimum distance of the

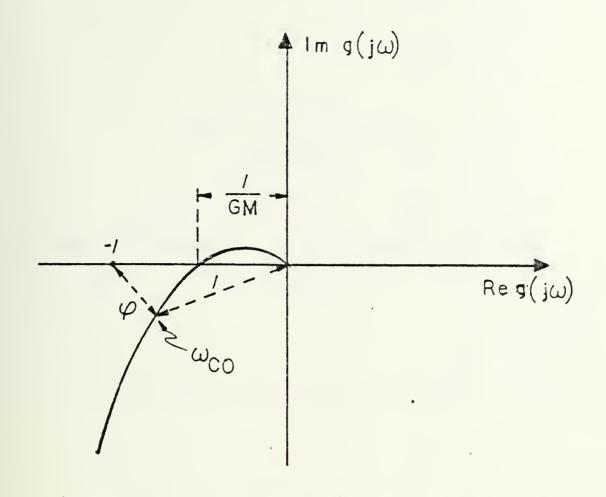

Figure 2.3 Nyquist Plot of Stable System.

locus of G(s)H(s) to the (-1,0) point is a measure of the system stability. This distance concept carries over directly to the MIMC system as will be shown in the next chapter. Examples of a multiplicative perturbation and an additive perturbation illustrate this idea. Figure 2.4 is an additively perturbed system. Figure 2.5 shows the Nyquist plot for this system. Assuming that the plant is itself stable and the perturbations are also stable the diagram may then be used to determine how near the system is to instability for the given perturbation.

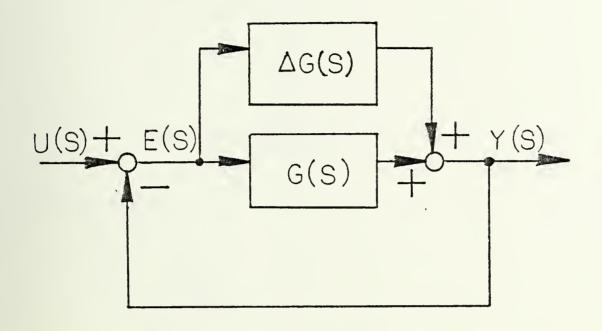

Figure 2.4 Additively Perturbed System.

Since the system is stable the (-1,0) point is encircled the correct number of times by the nominal plant. If the locus of  $g(j\omega)$  in the diagram is warped until it passes beyond the (-1,0) point then clearly the number of encirclements of this point will change and the system will become unstable, assuming the order of the plant is not changed by the perturbation. To keep the locus of points from moving beyond the (-1,0) point equation 2.1 must hold.

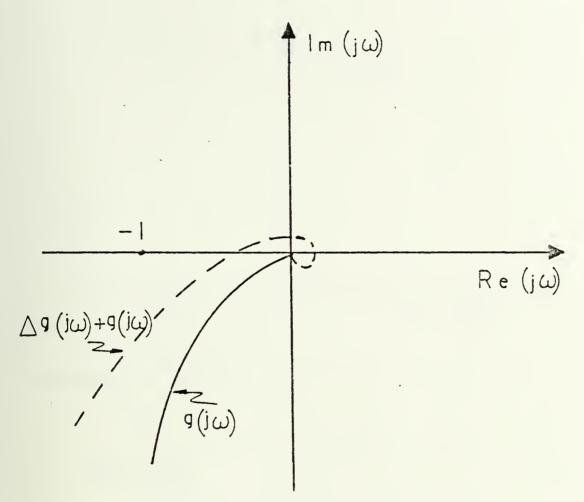

Figure 2.5 Additive Nyquist Plot.

$$|\Delta g(j\omega)| < |1 + g(j\omega)| \qquad (2.1)$$

This condition is illustrated in figure 2.6. The right-hand side of equation 2.1 is just the magnitude of the return difference transfer function of the nominal system. The multiplicative case is depicted in figure 2.7 with its associated Nyquist plot in figure 2.8. The requirement for stability is similar to the additive case and may be stated in equation 2.2

$$| \Delta g(j\omega) | < | 1 + (g(j\omega)^{-1}) |$$
 (2.2)

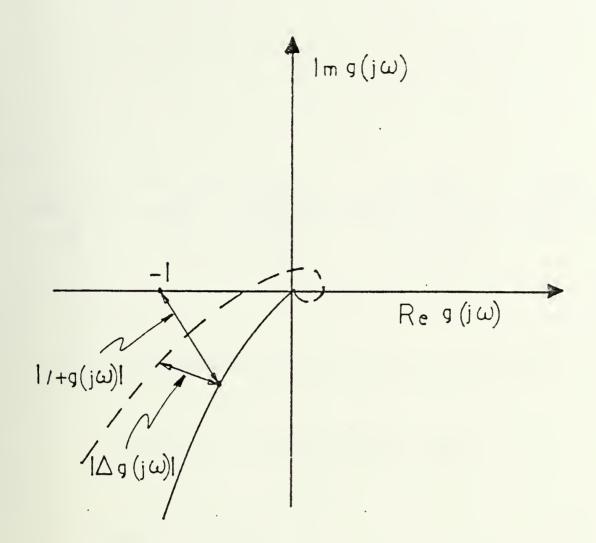

Figure 2.6 Nyquist for Inequality Additive Condition.

The above arguments will be applied again in Chapter 3 to develop multivariable stability and robustness properties.

The linear quadratic design has been the primary method employed in modern control design practice. In this method an optimal state feedback control law is developed to find a set of feedback gains that optimizes a chosen performance index. The performance index for the steady-state case is given in equation 2.3

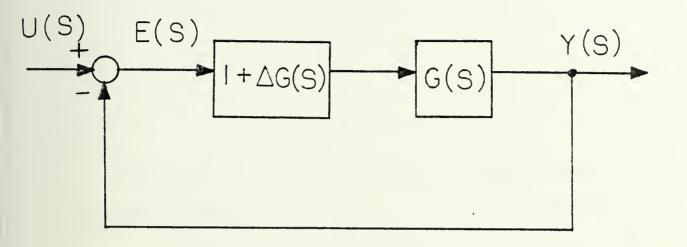

Figure 2.7 Multiplicative System.

$$PI = \int (\underline{x}^{\dagger}Q \underline{x} + \underline{u}^{\dagger}R \underline{u}) dt \qquad (2.3)$$

where the x'x term and the u'u term form quadratics. The Q and R matrices are chosen by the designer to provide the test compromise between the minimum error of the system and the minimum energy needed to control the system. The LQ method is based on the use of closed-loop state variable feedback for the control of the system. In the MIMO problem LQ methods have been used extensively because of their guaranteed stability margins with diagonal weighting matrices. For diagonal weighting matrices the LQ method yields a guaranteed phase margin of 60 degrees and -6 db to infinite gain margin.

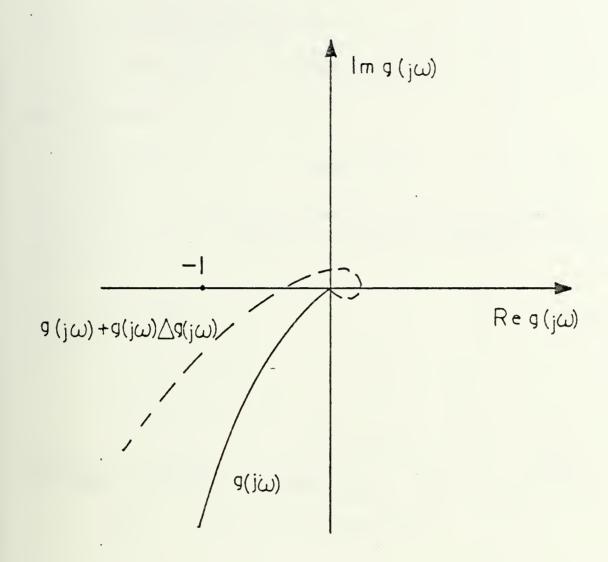

Figure 2.8 Nyquist Plot for Multiplicative System.

For SISO linear quadratic optimal regulators these stability margins can be developed from inequality 2.4 [Ref. 3]

$$|1 + f'(j\omega I - a)^{-1}k| \ge 1$$
 (2.4)

Writing the Kalman equation as 2.5

$$|1 + f'(sI-a)^{-1}b|^2 = 1 + (1/p)|G_{K}(s)|^2$$
 (2.5)

one has further

$$| 1 + G(s)H(s)|^2 = 1 + (1/p)|G_{\kappa}(s)|^2$$
 (2.6)

and for all  $s=j\omega$  and  $0\leq\omega<\infty$  the function  $(1/\rho)G_K(s)$  is greater than zero, therefore the Kalman inequality is shown to be 2.7.

$$| 1 + G(s)H(s)| > 1$$
 (2.7)

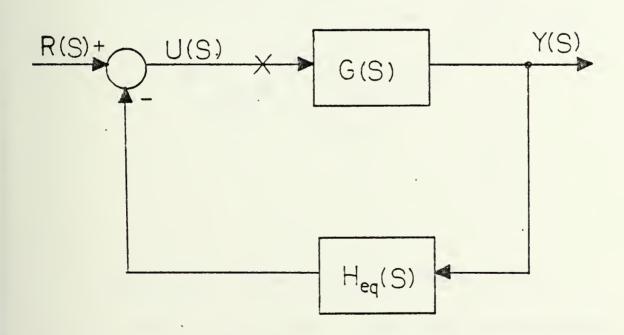

Figure 2.9 Typical Equivalent Feedback System.

The graphical interpretation of this result is that the polar plot of G(s)H(s) must remain outside the unit circle centered at the -1 + j0 point for all frequencies. Figure

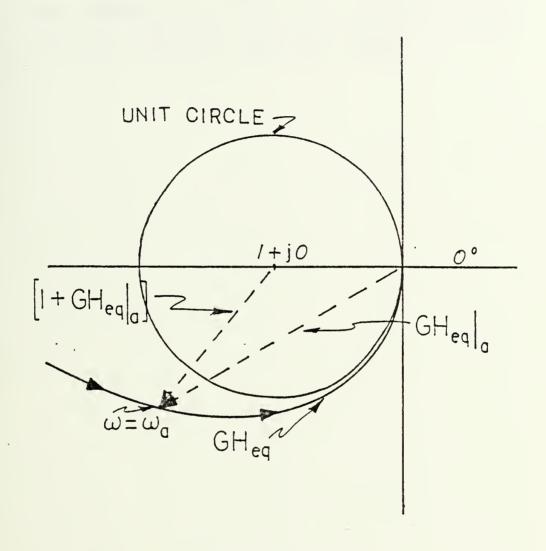

Figure 2.10 Folar Plot of an Optimal System.

2.10 shows such a polar plot. Since the optimal regulator with the loop broken at the input to the plant (denoted by the x in figure 2.9) does not penetrate the unit disk about -1 + j0 this means that the single input regulator will have

a phase margin of at least 60 degrees and a gain margin tolerance of fifty percent gain reduction and infinite upward margin. Further discussion of this property may be found in Anderson and Moore [Ref. 4]. With this hasic review of the concepts of stability and robustness in the classical SISO system complete, the next chapter will extend some of these basic concepts to the MIMO system.

## III. MULTIVARIABLE SYSTEMS

Linear quadratic design has performed relatively well in aircraft control concepts because of the ability to formulate the system state equation and to quantify acceptable performance indices for the system. Industrial applications for LC theory have been less successful and have led British researchers to look into forms of decoupled design methods. One of the primary methods used in multivariable design is to make the system totally decoupled. This method allows each loop to be designed as a separate entity by classical means. Cne of the primary difficulties with this method is problem of finding a compensator which will totally decourle the system. The method also suffers from effects of cross-coupled perturbation terms. A method that does not totally decouple the system but makes the design problem simplier by designing a compensator that only causes the diagonal terms of the transfer matrix to be dominant over all cff-diagonal terms has also been developed, [Ref. 5]. Classical frequency domain techniques are then used to design each loop of the system. The major difficulty with this and other single loop design techniques is their failure to account for cross-coupling perturbation terms that may interact between the loops. The individual loops may be highly robust in these designs but the overall system robustness may be low because of the loop interaction not accounted for in the design. This is the precise area that the singular value analysis has proven so beneficial in design . Singular value concepts may be applied to conventionally designed systems to assess their robustness. instance, if a system is designed by LQ methods the designer may then formulate the transfer function of the system and

assess the singular values of the return difference matrix of the system. If the minimum singular value is found to be low at some critical frequencies the designer can then modify the Q and/or R matrices chosen in the LQ performance index and recalculate the design. In this iterative fashion a robust design would be developed.

A generalization of the SISO Nyquist theory discussed in the previous chapter has been made for the MIMO problem. This generalization leads directly to the singular value concept. The generalization is expressed in the form of the multivariable Nyquist theorem which requires that a closed loop stable system have the same number of counterclockwise encirclements of the origin by the locus of the det (I+G (j $\omega$ )) as the number of open loop poles that are unstable. This theorem is formally stated as:

Let N[f(s)] denote the number of clockwise encirclements of (-1,0) by the locus of f(s) as s traverses the contour D of figure 3.1 in a clockwise sense. The closed-loop system will be stable if and only if for all R sufficiently large

$$N[f(s)] = -P$$

where

 $f(s) = -1 + \det[I+G(s)] = \varphi_{oL}(s)/\varphi_{cL}(s) -1 \text{ and}$  P = the number of closed right-half plane zeros of  $\varphi_{oL}(s).$ 

The application of the Nyquist theorem comes through the fact that a multivariable system will not be robust to modelling errors if the return difference matrix, I + G, is nearly singular for some frequency. If I + G is nearly singular a small change in G may make I + G exactly singular. This causes the det(I + G) to become zero and the Nyquist encirclement count to change indicating an unstable system. It is possible for very small changes in I+G to produce large changes in the determinant of I+G. The matrix I+G

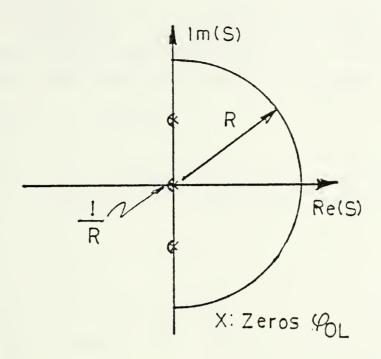

Figure 3.1 Nyquist D Contour.

has determinant 0.1/(s+a)<sup>2</sup>. If the element p<sub>2</sub>, is changed by only one percent to 9.9/s+a the determinant becomes 1.1/(s+a)<sup>2</sup> which is a significant change in the determinant value. Therefore, it is evident that det (I + G) is not an accurate measure of how near the return difference is to singularity. Researchers, in the field of controls [Ref. 6], [Ref. 7], [Ref. 8], [Ref. 9] have used singular value analysis to determine how near the return difference matrix is to singularity.

Since the number of encirclements of the Nyquist diagram changes as f(s) passes through the -1 point or when  $\det(\underline{I}+\underline{G})$  is zero it is important to find how near the return difference matrix  $\underline{I}+\underline{G}$  is to being singular. This nearness to singularity can be interpreted as closeness of the matrix  $\underline{G}$ 

to the critical point, -1. A quantity which can be used to express the nearness to singularity of the matrix is the minimum matrix singular value denoted by  $\mathcal Q$ . Given a matrix A the singular value may be expressed by equation 3.1

$$\mathcal{G}(A) = \min_{\lambda} \left( \lambda_{i} \left( \frac{A}{A} \right) \right)^{1/2}$$
(3.1)

where  $\lambda_i$  ( $\lambda^{"}_i\lambda$ ) is the eigenvalue of the complex conjugate transpose of  $\lambda$  times  $\lambda$ . A basic MIMO linear system is

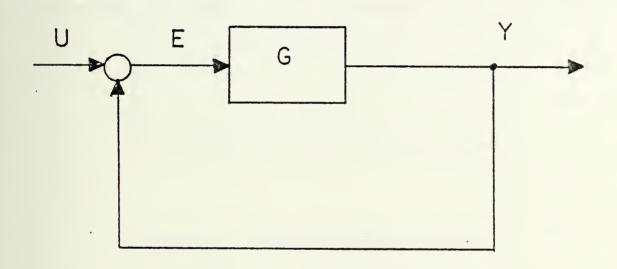

Figure 3.2 Basic Multi-input, Multi-output System.

depicted in figure 3.2. An additive perturbation to the plant is shown in figure 3.3. If the plant is stable before the perturbation is added to the system the Nyquist theorem will be satisfied and the locus of GH will not encircle the -1,0 critical point. When the perturbation is added to the system as long as the Nyquist locus is not forced to

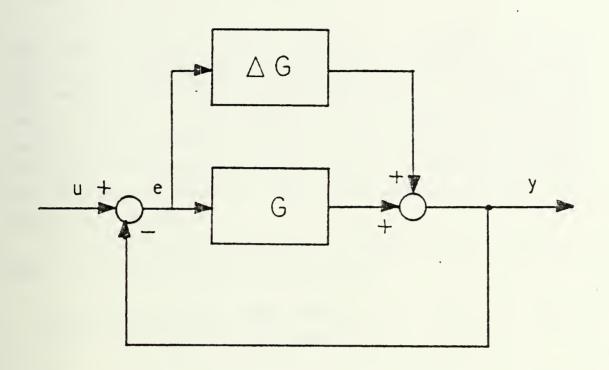

Figure 3.3 Additive Perturbation.

encircle the -1 point the system will remain stable. A sufficient condition, recalling the SISO discussion in chapter 2, for the perturbed Nyquist plot not to change encirclements is that the norm of the perturbation  $\triangle \mathcal{G}$  remain less than the norm of the return difference matrix as expressed in equation 3.2.

$$| | \Delta G(j\omega) | | < 1/| | (I+G)^{-1} | | |$$
 (3.2)

 $\omega$  ≥0 This condition will guarantee that the locus of the det(I+G) does not pass through the -1 point. If the 12 or Euclidean norm is assumed for this condition the equation

3.2 may be expressed in terms of singular values as equation 3.3.

$$\bar{\sigma}(\Delta G) \le \underline{G}(I + G) \tag{3.3}$$

This result states that as long as the maximum singular value of the perturbation matrix  $\triangle \mathcal{G}$  is below the minimum norm value of the return difference matrix the system will remain stable. The problem of guaranteeing robustness becomes that of finding the largest norm of the perturbation quantity, the largest singular value, for which the smallest norm or singular value of the return difference matrix will remain non singular.

The multiplicative form for a system such as figure 3.4 gives the similar norm equation in 3.4

$$||\Delta G(j\omega)|| < 1/|| (\underline{I} + (\underline{G})^{-1})^{-1}||$$

$$\omega \ge 0. \text{ which may be expressed as:}$$
(3.4)

$$\overline{G}(\Delta G) \leq \underline{G}(\underline{I} + \underline{G}^{-1}) \tag{3.5}$$

Singular value decomposition software is readily available to determine how near the matrix I+G or  $I+(G)^{-1}$  is to singularity.

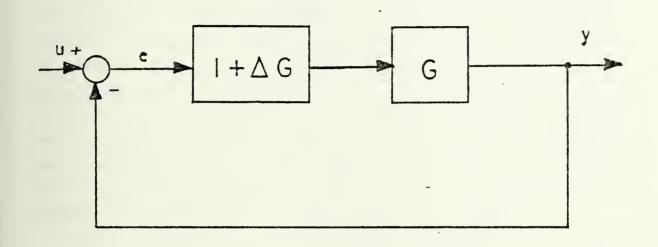

Figure 3.4 Multiplicative Perturbation.

## IV. OPTIMIZATION

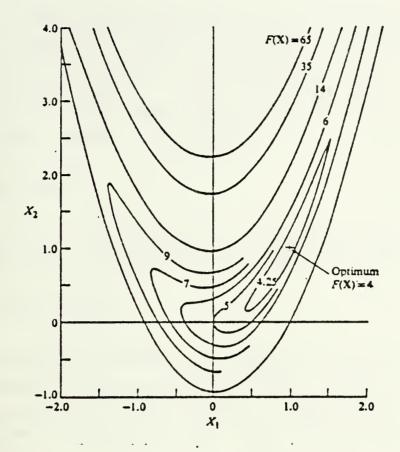

The purpose of this chapter will be to briefly describe several of the currently employed optimization techniques and the Automated Design Synthesis (ADS) program, [Ref. 10], which employs these techniques. In general, optimization implies finding the "best" possible solution to a problem. In actuality the best solution found by an optimization technique might really only be a "better" solution to the problem. The purpose of ADS and other optimization routines is to allow a rational search to be conducted to find the best possible design. The techniques of numerical optimization are used to logically vary the various parameters that affect the design until a good solution is found.

As an example of an unconstrained optimization problem consider the following problem developed in [Ref. 11]. The problem is to minimize the function

$$F(\underline{x}) = 10x, 4-20x, 2x_z+10x_z^2+x, 2-2x, +5$$
 (4.1)

F(x) is often called the objective function, the cost function or the penalty function. Since there are no conditions imposed on the design variables, x, and x<sub>2</sub>, and no additional limits imposed on the overall design, the problem is considered to be one of unconstrained minimization. Figure 4.1 represents this problem in the design space. From the figure it appears the optimum is near the point 1,1. Calculus may be applied to determine the optimum exactly. Taking the derivatives

Pigure 4.1 Design Space for Example Problem.

$$\partial F(x)/\partial x_1 = 40x_1^3 - 40x_1^2 + 2x_1^2 - 2 = 0$$
 (4.2)

$$\partial F(x) / \partial x_2 = -20x_1^2 + 20x_2 = 0$$
 (4.3)

and then solving the set of equations it is found that  $x_i = 1.0$  and  $x_i = 1.0$ .

If design conditions are imposed on the problem then the optimization becomes one of constrained function minimization. In other words, while the minimum of a function is still sought, this minimum must exist within the limits

imposed by the design conditions or constraints. The minimum of an unconstrained function will not necessarily be the same minimum for a constrained function.

As another example, also from [Ref. 11], a design is sought which gives the minimum weight of a particular column. This weight is expressed as:

$$W = \rho A h = \rho \pi D h \tag{4.4}$$

where  $\rho$  is the unit weight of the material and A the cross sectional area. The stress in the column is given by:

$$G = P/A = P/R Dt \tag{4.5}$$

without going into detail the design will be constrained by the allowable stress on the structure. Other constraints, Euler buckling and shell buckling, are also of interest to the designer of this column. The design problem is then stated as:

minimize 
$$W = \rho R$$
 Dth (4.6)

for the constraints

$$g(1) = \sigma / \overline{\sigma} - 1 \le 0 \tag{4.7}$$

$$g(2) = \sigma/\sigma_0 - 1 \le 0 \tag{4.8}$$

$$g(3) = G/G_S - 1 \le 0$$
 (4.9)

with D≥ 10e-06 and t ≥10e-06.

 $g(4) = t-D \le 0$  (4.10)

buckling stress and the shell buckling stress respectively.

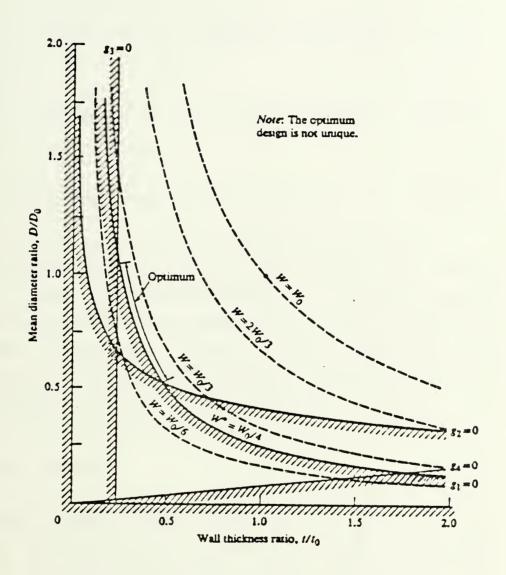

Figure 4.2 Design Space for Column Problem.

Figure 4.2 is a design space diagram for this problem. It is noted from the figure 4.2 that the optimum is not unique and can be any value along the arc noted as optimum in the figure.

The general optimization problem is then written as:

minimize 
$$F(x)$$
 objective (4.11)

subject to  $g_{j}(x) \le 0$  j=1, m inequality constraint (4.12)

$$h_{k}(x) = 0 k=1,1$$
 equality constraint (4.13)

$$x_i \le x_i \le x_i$$
 i=1,n side constraint (4.14)

where X = col(x1,x2,...,xn) is the design variable.

The methods used to solve this problem are usually iterative. After the establishment of an initial set of variables the optimizer will update this initial value until the cptimum values are found. Again ,borrowing from [Ref. 11], the iterative technique may be demonstrated by a simple example. Figure 4.3 is used to illustrate this problem. Given the initial data set X° the formula

$$X^1 = X^0 + \alpha^* S^1$$
 (4.15)

can be used to upgrade this estimate of X. The vector S is the search direction for the iteration and the scalar quantity  $\varkappa$  is the distance of the move in the S direction. Beginning at X° it is desired to reduce the objective function. The search for values of X that reduce the objective function is made in the S direction which in this example is the opposite of the gradient of the function at point X°. The choice of S could be arbitrary as long as it reduces the

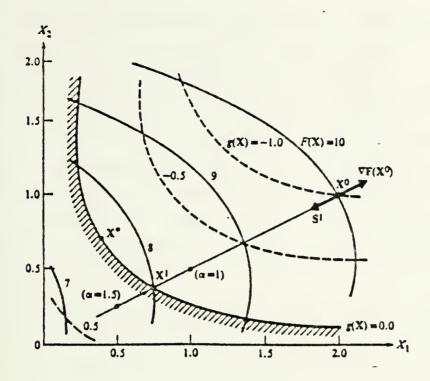

Figure 4.3 Illustrative Example for Iteration.

value of the objective. If S is chosen to be opposite the gradient of the objective then the search would be a steepest descent search. Once the direction is chosen then the scalar must be found to minimize the objective along this direction vector without crossing a constraint boundary. The technique for finding  $\varkappa$  is to evaluate X, the objective and the constraint functions for values of  $\varkappa$  using computer code and numerical interpolation to estimate  $\varkappa$ . This  $\varkappa$  value then gives the minimum value for F(X) along this search vector. Now that  $\varkappa$  for this direction is known the new equation becomes:

$$\underline{x}^2 = \underline{x}^1 + \alpha^* S^2$$
 (4.16)

and now  $X^1$  is used to start a new search in direction  $S^2$  and compute a new  $\alpha^*$  that continues to reduce the objective

function. These one dimensional searches are continued until no more reduction in the objective can be found. At this point no further design improvement is possible.

Crtimization techniques do not always lead to the absolute crtimum when applied to problems of practical interest. The reasons for this could be numerical ill-conditioning of the problem formulation or simply that there are multiple solutions to the problem. Because of these difficulties it may be adviseable to choose several different starting points for the optimization process and use engineering judgement as to the design most applicable to the problem under analysis.

Considering the unconstrained case first where the desire is to minimize the function  $F(\underline{x})$ , it is well known that  $F(\underline{x})$  will have a minimum where the gradient of  $F(\underline{x})$  is zero. That is:

$$grad(F(x))=0$$
 (4.17)

with the  $\nabla F(\underline{x})$  defined as:

grad 
$$(F(\underline{x})) = (\partial F(\underline{x})/\partial x_1, \dots, \partial F(x)/\partial x_n)'$$
 (4.18)

Figure 4.4 shows why this is a necessary condition but does not guarantee a global minimum. The gradient of  $F(\underline{x})$  is zero at all four points A,B,C,and D. However, only A and D are minima. A would be the global minimum for the function as defined here. D would be only a relative minimum. To check that the zero gradient corresponds to a minimum the Hessian matrix, i.e the matrix of second partial derivatives, can be examined for positive definiteness. A positive definite Hessian ensures a relative minimum. The only way to prove a global minimum for the function is to show that the Hessian matrix is positive definite for all design variables X. A test that is seldem possible to perform.

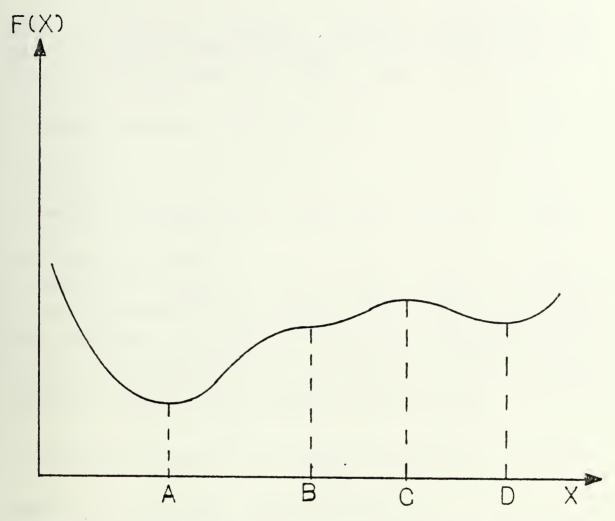

Figure 4.4 Plot of Various Points With Zero Gradient.

If the problem of minimization is a constrained problem the situation is different from that discussed above. The objective function gradient does not have to be zero at the optimum. Figure 4.5 illustrates this case. Using figure 4.5 and assuming a start at point A it is necessary to choose a search direction S which will reduce the objective function while not violating the constraint functions. Any direction that will reduce the objective is said to be useable. This is seen to be the half plane sector below the tangent to F(x) at point A. If a half plane to the right of the tangent to the feasible sector is formed. A combination of the two

conditions gives the useable, feasible sector where the search direction S must be chosen. In mathematical nomenclature the above argument may be stated as:

useable direction grad 
$$(F(X)) \cdot S \le 0$$
 (4.19)

feasible direction grad 
$$(g_{\cdot}(x)) \cdot S \le 0$$
 for all j (4.20)

for which  $g_{\cdot}(x) = 0$ .

Print B in figure 4.5 shows a point where the gradient of the objective and constraint point in exactly the opposite direction. At a point such as B the only search vector S that meets requirements for useability and feasibility is tangent to the constraint boundary and to a line of constant objective function. This condition is stated as:

$$\operatorname{grad}(F(\underline{x})) + \mathbb{Z}_{j}\operatorname{grad}(g_{j}(\underline{x})) + \mathbb{Z}_{m+k}\operatorname{grad}(h_{k}(\underline{x})) = 0$$
 (4.21)

where  $\lambda_{j} \geq 0$  and  $\lambda_{c+m}$  -unrestricted.

With this brief background in optimization complete the Automated Design Synthesis (ADS) program will be briefly discussed. More detail on the ADS routine can be found in [Ref. 10]. This code was developed as a follow-cn to the successful CONMIN code [Ref. 12] developed by Vanderplaats. It is designed as a black box optimizer which allows the user to choose combinations of one dimensional search, optimization algorithm and optimization strategy. These will be discussed later. For the user with specific requirements the code may be tailored by parameter modification to meet specific requirements. For the work done in this thesis it was assumed the user of the code has no detailed knowledge of optimization and will want to use the code in the

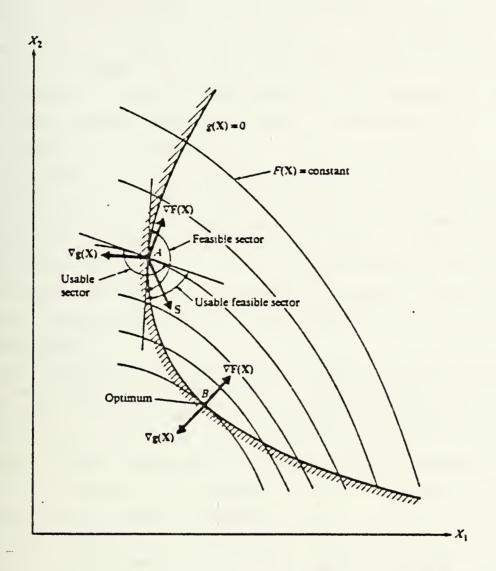

Figure 4.5 Constrained Optimization Example.

simplest form. As such, the ADS calls made from the main program use only default parameters and first forward finite difference gradients. Should analytical gradients be available the user could use them within the code if desired with no difficulty. The calls made by the user to the ADS routines specify several important aspects of the problem solution. The user may call for an optimization strategy to be used in the routine. This is not required and its use

depends on the problem. These strategies are discussed in [Ref. 10]. Two strategies used most often in the analysis done for this thesis have been sequential unconstrained minimization using quadratic exterior penalty function and the augmented Lagrange multiplier (ALM) method. Others available include sequential linear programming and sequential quadratic programming.

The basic optimizer is also chosen by the user from two unconstrained and three constrained optimization algorithms. The unconstrained algorithms are Fletcher-Reeves conjugate directions, Davidon-Fletcher-Powell (DFP) variable metric method and the Broydon-Fletcher-Goldfarb-Shanno (BFGS) variable metric method. The method of feasible directions and robust feasible directions are available for constrained minimization.

The user has available several types of one dimensional searches using Golden Section or polynomial approximation techniques. The ADS code has tailored these one dimensional search algorithms for the unconstrained and constrained cases, allowing the user to make appropriate choices for the type of problem to be solved. Figure 4.6 shows the basic organization of the ADS program.

Since it is not the purpose of this chapter to cover the subject of optimization in detail all the possible routines in ADS will not be discussed. A few of the routines found to work well for the work completed in this thesis will be briefly described, however. There are several methods of optimizing functions of one variable or one dimensional searches. For instance a large number of points, n, could be chosen and the function  $F(\underline{x})$  evaluated at each point. The point corresponding to the smallest value of  $F(\underline{x})$  could then be considered the optimum value of the one dimensional search. This method is hit and miss and better methods

locating optimum points can be used. The methods used in ADS are Gold $\epsilon$ n Section and polynomial interpolation.

Golden Section search methods are easy to program on the digital computer and do not require continuous derivatives. They have a known convergence rate and are reliable for poorly conditioned problems. The major drawback of the Golden Section routines is the large number of function evaluations require. The Golden Section algorithm is simply illustrated through the use of figure 4.7 Assume that  $X^0$  and  $X^1$  are known to be bounds on the curve's minimum value. Also, the function values of F(x),  $F^0$  and  $F^1$ , are evaluated and known at these points. By picking two intermediate points  $X^2$  and  $X^3$  where  $X^2$   $< X^3$  and evaluating the function

Pigure 4.7 Golden Section Diagram.

at these points a bound on the minimum may be modified. Since F<sup>2</sup> for this figure is larger than F<sup>3</sup> the point X<sup>2</sup> forms the new lower bound. The minimum is now between X<sup>2</sup> and X<sup>1</sup>. If the function F<sup>4</sup> at X<sup>4</sup> is determined and shown to be larger than F<sup>3</sup> then X<sup>4</sup> becomes the new upper bound on the minimum. By repeating this procedure the bounds may be narrowed to any desired tolerance. The Golden Section rule is applied to this problem to reduce the bounds in the quickest possible time. By appropriately picking the values of X's at which each function evaluation is made an efficient algorithm that uses the ratio proportion of the Golden

Section,i.e.  $X^2/X^1 = 1.62803$  is developed. By choosing a value  $\mathcal{T}$  based on this Golden Section rule where  $\mathcal{T} = 0.38197$  estimates for interior points  $X^2$  and  $X^3$  can be made as:

$$X^{2} = (1 - 2) X^{0} + 2 X^{1}$$
 (4.22)

$$X^{3} = ? X^{0} + (1 - ?) X^{1}$$
 (4.23)

As each new bound is found the process repeats until the accepted level of convergence is reached.

The polynomial interpolation method is accomplished by first fitting a polynomial curve to the points about where the minimum is desired and then finding the minimum of the polynomial function. For example if the function F(X) is approximated by a quadratic as:

$$F = a_0 + a_1 X + a_2 X^2$$
 (4.24)

Then the value of X,  $X^*$ , where F' is zero can be shown to be:

$$x^* = -a, /2a_2$$
 (4.25)

If a z is positive then F will be minimum. Other degrees of polynomials may be used in similar fashion.

Now that the basic one dimensional search methods have been reviewed the next step is to examine the basic optimization routines. First, the unconstrained case will be reviewed. The optimum X is at the point where

grad ( 
$$F(X^*)$$
) = 0 (4.26)

Several zero order methods exist for the purpose of finding the minimum value. These include random search, Powell's method and Box's method. Since ADS does not use these methods they will not be discussed.

Automated Design Synthesis makes use of first order methods which will now be discussed. The steepest descent method is best known, but poor in performance. Just as the name implies a search direction is chosen opposite the gradient of the objective function. At iteration 0

$$S^{\circ} = -\operatorname{grad}(F(X^{\circ})) \tag{4.27}$$

Figure 4.8 shows this algorithm geometrically. Note that the method simply stair steps its way down the "hill" to the valley or minimum. ALS uses the Fletcher-Reeves modification to steepest descent. In this routine a conjugate direction is chosen to improve the speed of the search. Figure 4.9 shows how this method tracks to the solution.

The variable metric methods listed earlier are usually more powerful than Fletcher-Reeves because they store information that allows the algorithm to approximate the inverse of the Hessian matrix or second derivative. For further discussion of these methods see [Ref. 11] or other similar optimization texts.

ALS employs two direct methods for constrained minimization. One method is that of feasible direction and the other is the method of robust feasible direction. Since these two methods were seldom employed within the work presented in this paper they will not be discussed.

The methods chosen to handle the constrained minimization problems formulated in this thesis are referred to as Sequential Unconstrained Minimization Techniques (SUMI).

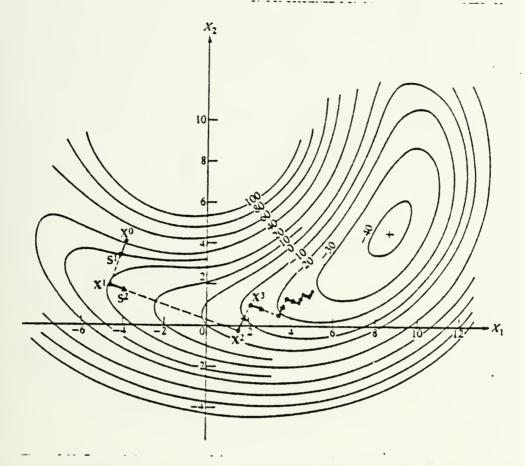

Figure 4.8 Steepest Descent Algorithm.

SUMT methods are methods which formulate the objective function and the constraint functions into an augmented objective function and then solving the problem as if it were an unconstrained optimization task. ADS employs interior and exterior penalty function techniques as well as an Augmented Lagrange Multiplier (ALM) technique.

The exterior penalty function method is incorporated by forming a penalty from the constraint equations. This penalty is of the form:

$$P(\underline{x}) = \sum_{j=1}^{m} \max(0, g_{j}(x))^{2} + \sum_{k=1}^{l} (h_{k}(\underline{x}))^{2}$$
 (4.28)

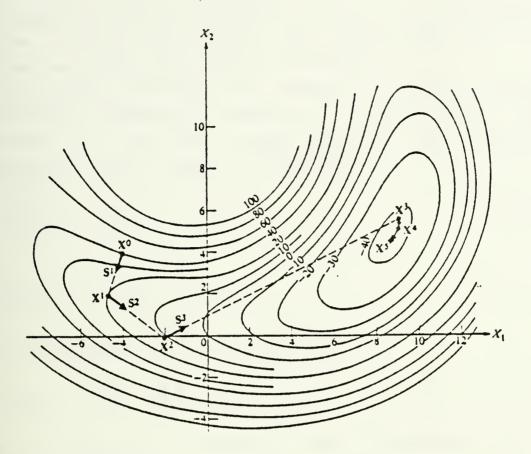

Figure 4.9 Fletcher-Reeves Conjugate Direction Algorithm.

From this equation it is obvious that  $P(\underline{x})$  is zero if all the constraints are satisfied. That is, if  $g_{\underline{x}}(\underline{x}) \leq 0$  and  $h_{\underline{x}}(\underline{x}) = 0$ , then all conditions of the penalty function are satisfied. If an element of the penalty function is violated then the penalty increases as the square of the violated constraint. A pseudo or augmented objective function is formulated where:

$$\Phi(\underline{x}, r_p) = F(\underline{x}) + r_p P(\underline{x})$$
(4.29)

The constant r, is a weighting factor for the penalty. It is adjusted with ADS as the optimization proceeds to allow the program to systematically converge to an optimum solution.

One disadvantage of this method is that if the optimizer is stopped short of the optimum the design will be in the infeasible region and probably not useful.

Criginally developed as a method to solve equality constrained problems the version of ALM in ADS has been modified to work with both equality and inequality constraints. The statement is as follows:

minimize 
$$F(x)$$
 (4.30)

subject to 
$$h_{K}(\underline{x}) = 0 k=1,1$$
 (4.31)

Next a Lagrangian is created such that

$$L(\underline{x},\lambda) = F(\underline{x}) + \sum_{K=1}^{\ell} \lambda_K h_K(x)$$
 (4.32)

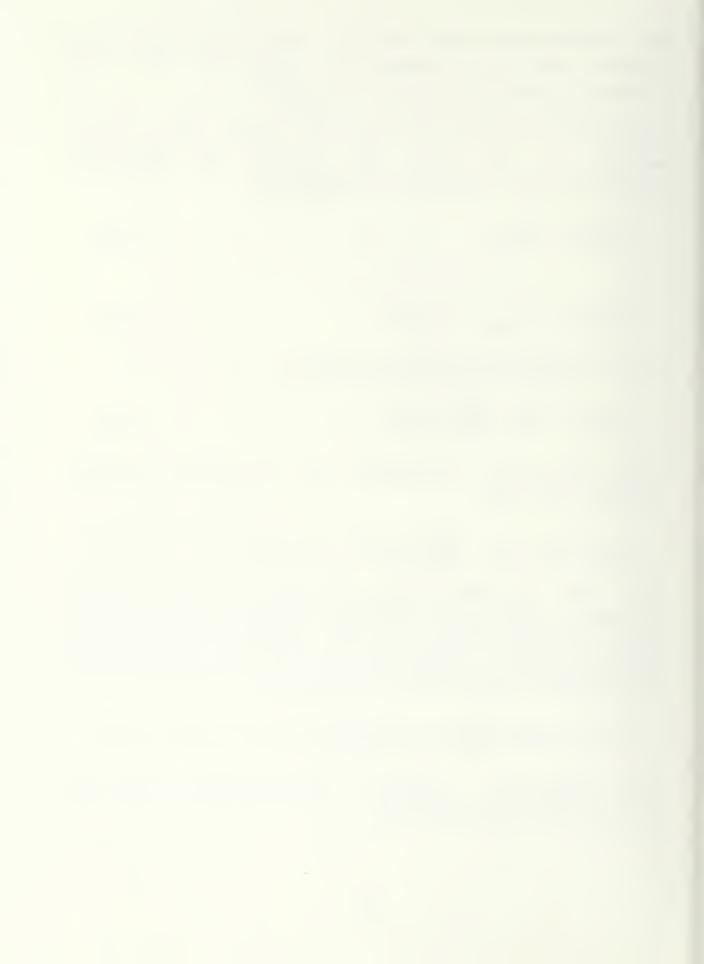

Then the equation is augmented with an exterior penalty function such that

$$A(x,\lambda,r_p) = F(\bar{x}) + \sum_{k=1}^{\ell} (\lambda_k h_k(\bar{x}) + r_p(h_k(\bar{x}))^2) \qquad (4.33)$$

The power of this method is that in theory precise constraint matching is possible whereas in the exterior penalty function method it is not. The full details of the method will not be covered here, however, the final form of the objective function will be included:

$$A(\underline{x},\lambda,r_{p})=F(\underline{x})+\sum_{s=1}^{m}(\lambda_{s}y_{s}+r_{p}y_{s}^{2})+\sum_{k=1}^{g}(\lambda_{k}h_{k}(\underline{x})+r_{p}(h_{k}(\underline{x}))^{2})(4.34)$$

where  $f = \max(g_j(x), -\lambda_j/2r_p)$ , and the update formulas for the Lagrange multipliers are:

$$\lambda_{j}^{P+1} = \lambda_{j}^{P} + 2r_{p} (\max(g_{j}(x), -\lambda_{j}/2r_{p})) \quad j=1, m$$
 (4.35)

$$\lambda_{k+m}^{P+1} = \lambda_{k+m}^{P} + 2r_{p}h_{k}(x) \quad k=1,1$$
 (4.36)

With this brief review of optimization and the ADS program completed the next chapter will discuss the program development for this thesis research.

## V. OPTIMIZATION DESIGN PROCEDURE

Tc accomplish the task of designing a control system with acceptable time domain performance and robustness characteristics in a straight forward manner a numerical optimization technique was chosen as the method of implementation of the design algorithm. Using numerical procedures to adjust selected design variables, in this case the feedtack and/or filter gains, a desired level of performance can te achieved. This level of performance is actually a combination of time domain performance and robustness or frequency domain performance. By establishing the criteria the system performance in terms of an optimization objective and constraint functions a versatile procedure can te developed to set the system feedback gains and affect an acceptable design in terms of performance and robustness. The pcle placement and robustness (POPLAR) design procedure uses pole placement to establish a designer selected performance level and then a minimum singular value level to establish the robustness.

The pole placement portion of the procedure will be discussed first. The pole placement technique was chosen because it was relatively easy to implement through a numerical optimization routine. By using this numerical procedure it is also simple to incorporate robustness into the procedure along with the performance requirements. A numerical technique similar to one posed in [Ref. 13] was chosen for the pole placement algorithm. An unconstrained optimization routine from the IBM IMSL library was used for this program. The routine, a Newton method, uses adjustments to the output feedback gains to reduce the size of an objective function. This objective function was expressed as a function of the

pole location of the system and as the objective was reduced the poles were moved toward the desired locations. To provide more versatility in the pole placement algorithm a method that can use constraint functions as well as unconstrained optimization was chosen for this program. The designer may use either objective, constraint or a combination of functions to secure the desired pole locations. As currently implemented in the program the cost or objective portion of the pole placement procedure is constructed as equation 5.1

OBJ = 
$$\sum_{i=1}^{J} (\lambda_{R_{0,i}} - \lambda_{R_{i}})^{2} + (\lambda_{I_{0,i}} - \lambda_{I_{i}})^{2}$$
 (5.1)

where

 $\lambda_R$  = real eigenvalue

 $\lambda_{I}$  = imaginary eigenvalue

 $\lambda_{k_b}$  = desired eigenvalue location

 $\lambda_{I_{h}}$  = desired eigenvalue location

The constraint formulation is a function that must be kept negative or the constraint is violated. It is written as equation 5.2

$$g(j) = \sqrt{(\lambda_{e_{ij}} - \lambda_{e_{ij}})^{2} + (\lambda_{I_{o_{ij}}} - \lambda_{I_{i_{j}}})^{2}} - r$$
 (5.2)

where r is a tolerance circle established as a function of pole placement position. Since the aim of the optimizer is to keep g negative any time the  $\lambda$  function of the constraint is greater than r the constraint will become active, i.e. violated. The optimizer will then attempt to move the constraint to the inactive status by adjusting the design parameters of the system.

Consideration of implementation of the frequency domain or robustness portion of the design procedure begins with the concept of MIMO phase and gain margins. Several useful theorems on singular value analysis of multiloop systems are

presented in [Ref. 8]. One of these theorems relates the matrix singular value of the return difference function to a parameter,  $\alpha$ , and further shows that as long as the maximum singular value of the perturbation function ( $L^{-1} - L$ ) remains less than this  $\alpha$ , the system remains stable. The value of  $\alpha$  is then related to gain and phase margins of the MIMO system. The relationship developed is given in equations 5.3 and 5.4:

gain margin = 
$$GM = 1/(1+\aleph_0)$$
 (5.3)

phase margin = PM = 
$$\pm \cos^{-1}(1-\alpha_0^2/2)$$
 (5.4)

provided that equation 5.5 holds.

$$\sigma(I+G) \geq \alpha_0 \tag{5.5}$$

for some &o≤1

These phase and gain margins are guaranteed in every loop simultaneously.

Universal gain and phase margin curves, [Ref. 14], based on the minimum singular values of the return difference matrix are developed from equation 5.6.

$$(I^{-1}-I) = \max \sqrt{(1-1/k_n)^2 + 2/k_n (1-\cos \theta_n)}$$
 (5.6)

for all n with  $k_n > 0$ . These curves shown in figure 5.1 allow the designer to pick a singular value that corresponds to a specific gain and phase margin for a given system. In addition to the universal gain and phase plot [Ref. 15] developes an optimizer solution for formulating a robust controller using the CONMIN algorithm [Ref. 12].

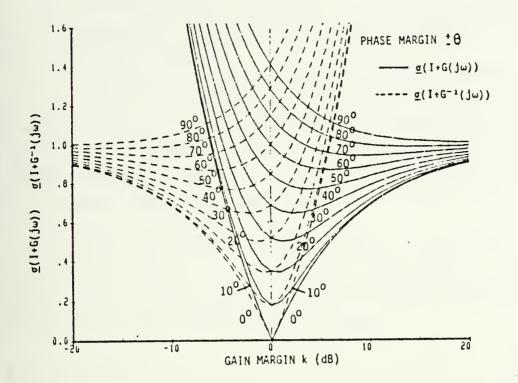

Figure 5.1 Universal Gain and Phase Singular Value Plot.

Since the universal curve in figure 5.1 provides a convenient method of specifying gain and phase margins in terms of singular values the robustness portion of the pole placement and robustness design procedure uses the minimum singular value level of the return difference matrix to determine the robustness. The minimum singular value level is formulated as an objective or constraint function in equation 5.7

$$J = \sum_{j} (\max(0, (G_{j} - G(j\omega, p)))^{2}$$
 (5.7)

The optimization procedure may be used to change feedback gains until the minimum singular value is raised above this desired design level. Although the same formulation can be used as a negative constraint function it has not been implemented as such within this program. There are numerous

ways the singular value formulation could be implemented within the program by changes of the code if design requirements forced such changes.

The pcle placement and robustness design program is based on the ADS code discussed in Chapter 4 to implement the design variable selection procedures. The pole placement and robustness program consists of two separate programs. The first program is used to provide designs for state or output feedback problems while the second program is used for observer or filter designs.

For the state or cutput feedback design program the user must input the plant matrices A,B,C and initial starting values for the feedback matrix F. The matrices correspond to the following linear differential system:

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u} \tag{5.8}$$

$$\underline{y} = \underline{C}\underline{x} \tag{5.9}$$

$$u = -Fx \tag{5.10}$$

A feed-forward matrix has not been considered in the current program. A feed forward matrix could be added to the procedure if required for specific design cases.

As the design program is currently coded the user may run output feedback or state feedback design by specifying the C matrix as the diagonal(I) matrix for state feedback. The program relies on initial starting values of the feedback gains, F. As discussed in Chapter 4 there is no guarantee that the optimum found by the procedure each time is the global optimum or that the procedure will always

converge to an acceptable solution. The ability to select acceptable starting values for the feedback gains will make the procedure more efficient in operation. As currently employed, the program is used to obtain pole placement and robustness for a given set of starting gains and a selected optimization routine from the ADS program. If the optimizer is not able to meet the desired design goals on this program run two options are available. First, change to a different optimization routine from the list of available ADS routines and rerun the problem. This was usually successful in improving the design. Second, the designer uses a new set of starting values for the feedback gains and repeats the design procedure. Both options might be used on particularly difficult cases.

The pole placement and robustness design procedure has consistently been able to find improved designs; however the program does not always yield acceptable designs. Certain problems require changes in the optimizer routine and modification in the initial feedback gain starting values in order to obtain acceptable designs. Using the IBM 3033 time share system the pole placement and robustness routine requires about ten CPU seconds to work a second order problem and on the order of 15 to 60 CPU seconds to run a forth order problem. The actual amount of time varies with optimization requirements and time share utilization.

The observer robustness design program requires two passes of the ADS program. In the first pass the feedback gains, F, of the controller are computed to obtain the desired pole locations. The second pass of the ADS routine is used to adjust the observer gains to recover the system robustness. The two pass procedure was chosen because it allows a smaller number of design variables at each stage of the optimization and much more efficient computer usage. Figure 5.2 shows how the observer is implemented. This diagram is algebraicly stated as:

$$\dot{\hat{x}} = \begin{bmatrix} A & -BK \\ FC & A_c - BK \end{bmatrix} \begin{bmatrix} x \\ \hat{x} \end{bmatrix} + \begin{bmatrix} B \\ B \end{bmatrix} \mathbf{r}$$

$$A_c = A - FC$$
(5. 11)

where  $\underline{x}$  is the state,  $\hat{\underline{x}}$  is the estimator variable,  $\underline{\underline{F}}$  is the feedback gain and  $\underline{K}$  is the observer gain. The design of the feedback gains and the observer gains are accomplished as separate quantities in keeping with the separation prin-

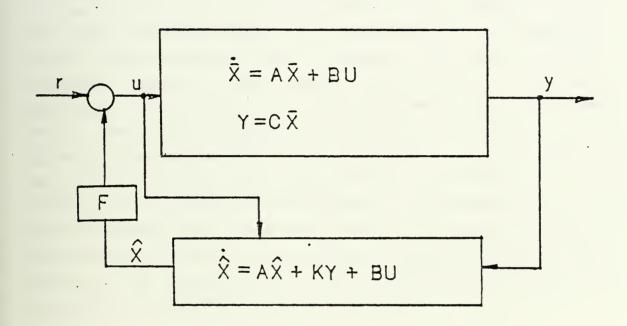

Figure 5.2 Observer Implementation.

ciple. In using the pole placement and robustness design procedure for the observer system, initial values of the F and K matrices must be input. The same or different optimization techniques from ADS may be employed.

The routines contained in this thesis have been based on the input additive singular value level. The pole placement and robustness design algorithm computes input additive,

output additive, input multiplicative, and output multiplicative singular values. Any of these singular values can be incorporated into the objective or constraint formulations but have not been for this version of the program.

In summary, the pole placement and robustness design procedure is a straight forward numerical optimization procedure for the practical application modern MIMO system analysis. The new aspects of the procedure are the implementation of both pole placement and robustness criteria within the same design program. The versatility of the pole placement and robustness design is obtained by incorporating a state of the art crtimizer routine ADS, with currently available singular value computation routines. Using the optimizer format for the pole placement and robustness design gives the designer the ability to modify variables directly that affect both the time domain or performance of the system and the frequency domain or robustness of the system. The numerical optimization incorporated into the pole placement and robustness design is flexible enough to incorporate the double pass design technique using the separation of the feedback and filter gains to obtain robustness recovery for observer based controllers.

## VI. INTRODUCTORY PROBLEM

The purpose of this introductory problem is to review some results of modern multivariable robustness theory using a simple problem. This same simple system is then used as a test problem for the optimization technique developed for this thesis. The problem provides excellent insight into the cross-coupling problem and demonstrates how effectively the pole placement and robustness design procedure can be in dealing with the cross perturbation terms.

The problem chosen for this introductory analysis comes from [Ref. 9]. Figure 6.1 is a diagram of this basic system. In this problem a simple plant is specified by the following linear system:

$$\begin{bmatrix} \dot{\mathbf{x}} \, \mathbf{1} \\ \dot{\mathbf{x}} \, \mathbf{2} \end{bmatrix} = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} \mathbf{x} \, \mathbf{1} \\ \dot{\mathbf{x}} \, \mathbf{2} \end{bmatrix} + \begin{bmatrix} 1 & \mathbf{b}_{12} \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \mathbf{u} \, \mathbf{1} \\ \mathbf{u} \, \mathbf{2} \end{bmatrix}$$

$$(6.1)$$

$$y1 = x1$$

$$y2 = x2$$

$$(6.2)$$

A feedback compensation of the form of equation 6.3 was assumed.

$$\begin{bmatrix} u & 1 \\ u & 2 \end{bmatrix} = -\begin{bmatrix} x & 1 \\ x & 2 \end{bmatrix} + \begin{bmatrix} u & c & 1 \\ u & c & 2 \end{bmatrix}$$
 (6.3)

Which gives a closed-loop system, equation 6.4

$$\begin{bmatrix} \dot{\mathbf{x}} \, \mathbf{1} \\ \dot{\mathbf{x}} \, \mathbf{2} \end{bmatrix} = \begin{bmatrix} -2 & h_{\mathbf{z}} \\ 0 & -2 \end{bmatrix} \begin{bmatrix} \mathbf{x} \, \mathbf{1} \\ \mathbf{x} \, \mathbf{2} \end{bmatrix} + \begin{bmatrix} \mathbf{1} & h_{\mathbf{z}} \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \mathbf{u} \, \mathbf{c} \, \mathbf{1} \\ \mathbf{u} \, \mathbf{c} \, \mathbf{2} \end{bmatrix}$$
(6.4)

This system has eigenvalues at -2 ,-2 and is therefore stable. Using equation 6.5

$$G = C(SI-A)^{-1}B$$
 (6.5)

the transfer matrix may be written as equation 6.6.

$$G = \begin{bmatrix} 1/s+1 & b_{12}/s+1 \\ 0 & 1/s+1 \end{bmatrix}$$
 (6.6)

which gives the return difference matrix, equation 6.7.

$$I+G(s) = \begin{bmatrix} s+2/s+1 & f_{12}/s+1 \\ 0 & s+2/s+1 \end{bmatrix}$$
(6.7)

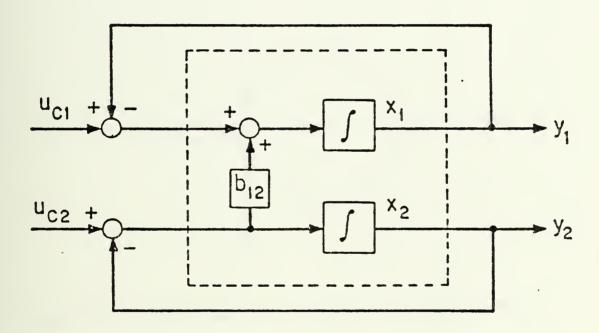

Figure 6.1 Basic Multi-input Multi-output System.

The problem shows the inadequacies of classical methods in establishing the robustness of the system. A brief review

of the results will be presented. Using the return difference matrix (I+G), the determinant may be written as equation 6.8.

$$\det(I+G) -1=2s+3/(s+1)^2$$
 (6.8)

Therefore, the multivariable Nyquist diagram will be as

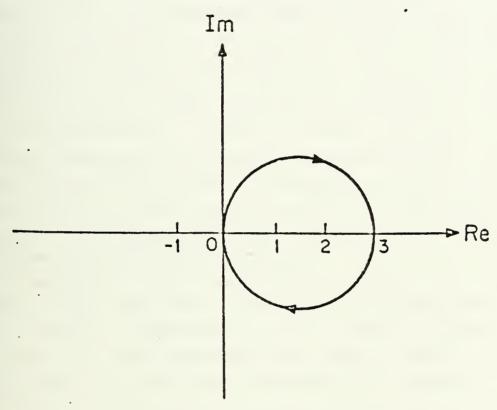

Figure 6.2 Multivariable Nyquist for 2s+3/(s+1)2.

shown in figure 6.2. The diagram does not encircle the (-1,0) point and is indicative of a closed-loop stable system. Considered as a SISO system one has a gain margin of -1/3 to  $\infty$  and a phase margin of  $\pm 106$  degrees. Under this criteria one can conclude that this is a good design. This will be shown later not to be the case.

Multi-input systems are often designed a loop at a time. Applying loop design to the system the transfer function for either loop taken separately becomes equation 6.9

G = 1/s + 1 (6.9)

Figure 6.4 shows the Nyquist diagram of this problem. Using this Nyquist diagram the system is indicated to be stable and have phase and gain margins of  $GM=(-1,\infty)$  and  $FM=(\pm 180)$ . This analysis does not show the true nature of the robustness of the system. Since the factor b is not a parameter in either of the Nyquist curves it plays no part in the stability determination using these diagrams.

Using the criteria of singular values discussed in Chapter 3 a measure of the nearness to instability for this problem may be obtained by plotting the minimum singular value of (I+G), G. (For numerical calculations a value of I+G), I+G is assumed). Figure 6.3 shows the plot of this value vs. frequency. This gives a minimum singular value of about -23 db or 0.071 which corresponds to a gain margin of about 0.93 to 1.08 and a phase margin of I+G degrees. These phase and gain margins are quite small and are evident in the cross-feed perturbation problem.

A perturbed system as shown in figure 6.5 can be produced which will lead to stability problems with very small values of perturbation. The closed-loop system if perturbed by a small perturbation,  $5/b_{12}$ , where  $b_{12}$  is a large number, will have as a characteristic equation, equation 6.10

$$(sI-A) = s^2 + 4s + 9$$
 (6.10)

with the eigenvalues of  $s=-2\pm\sqrt{5}$ . There is one positive root in this solution and the system is unstable.

To determine the nature of the robustness of this system the return difference matrix must be considered. If the return difference matrix of the transfer function ( $\mathbb{I}+\mathfrak{G}(j\omega)$ )

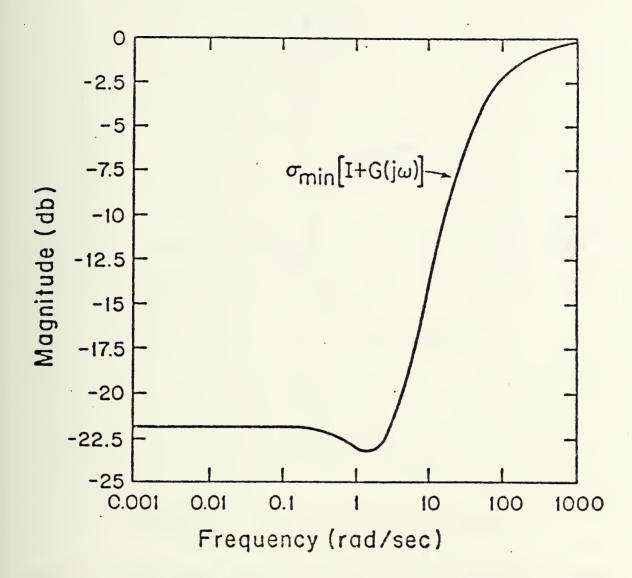

Figure 6.3 Minimum Singular Value Plot, Example Problem.

is nearly singular at some frequency  $\omega_{\bullet}$ , then the multivariable system will not be robust with regard to any modelling errors within the system. This is because any small change in  $G(j\omega)$  can then make  $I+G(j\omega)$  singular and the det (I+G) becomes zero, thus changing the encirclements of the Nyquist stability point and indicating a system instability. Using equation 6.1 the pole placement and robustness design method

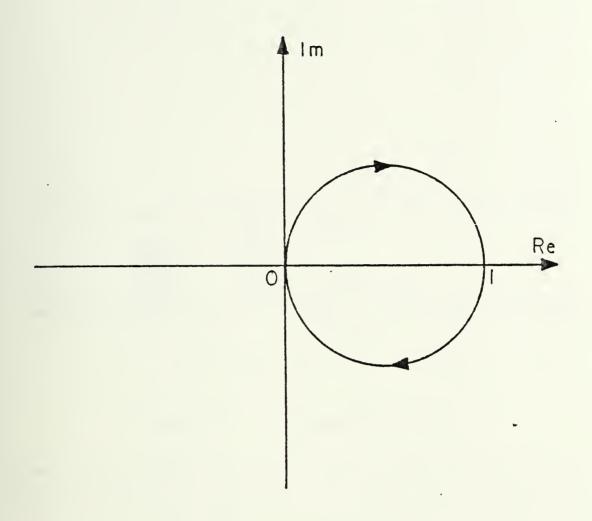

Figure 6.4 Nyquist Diagram of 1/s+1.

can be demonstrated. The first step is to establish a baseline for the design. The state unity feedback model in this
simple problem gives pole locations of -2 and -2. This set
of eigenvalues -2, -2 were chosen as the baseline for the
system. Since a second order system requires only two feedback gains to place the poles, the diagonal feedback gains
were chosen for pole placement purposes. The pole placement
and robustness design program was then used to place the
poles and in the process obtained the gains required to do
this (1,1). A plot of some of the singular value criteria
obtained is shown in figure 6.6. Pole-zero plots of the

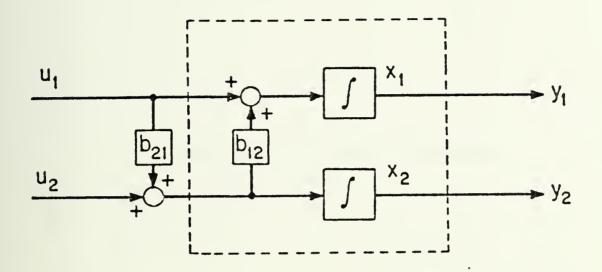

Figure 6.5 Perturbed System.

closed-loop transfer functions of the closed-loop transfer matrix are shown in figure 6.7. In this case the poles and a zero are clustered about the -2 point and in the input two to output one channel a zero is located at the -1 point on the pole-zero diagram. This point closely corresponds to the minimum singular value frequency. The only significant observations are the ability of the pole placement and robustness routine to place the poles and the relatively poor singular values indicative of low robustness.

Since there is a requirement for two feedback parameters to set the poles of a second order system there should be no additional freedom in design to account for robustness. Case two was a run to demonstrate this fact. Again allowing only two design variables for the problem the pole placement and robustness design program was run but with an objective function formulated to adjust the singular value above a

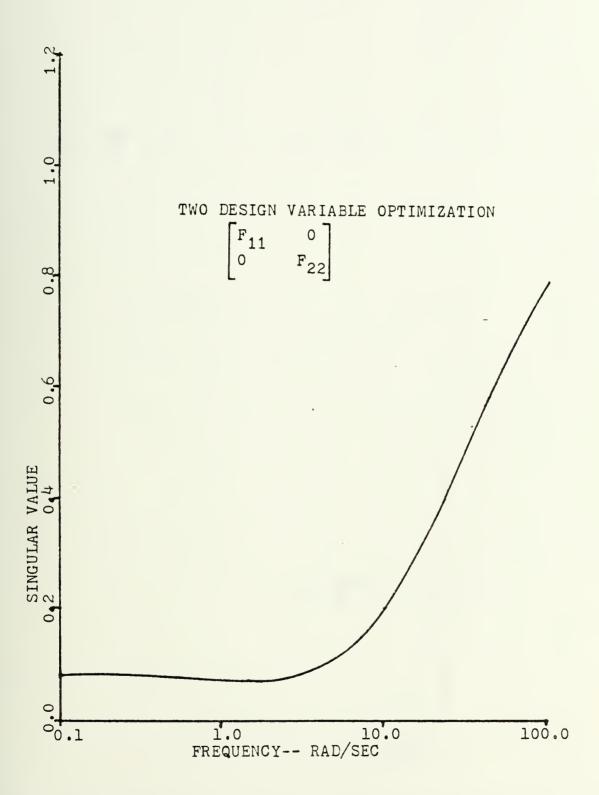

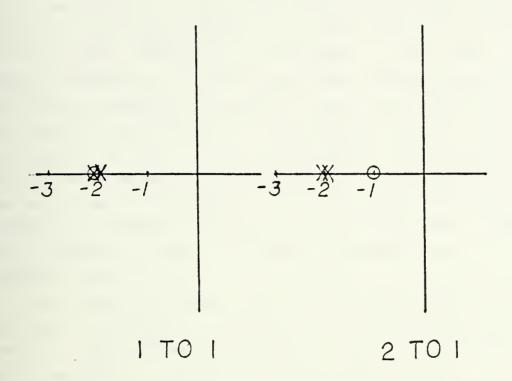

Figure 6.6 Singular Value Plot for Simple Problem.

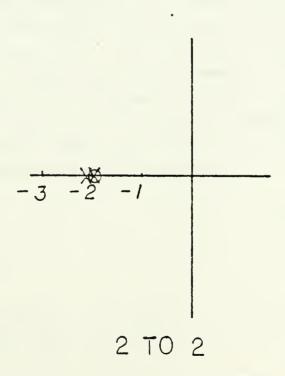

Figure 6.7 Closed-loop Poles for Pole Placement Only Case.

base level of 0.6. This level would correspond, using the universal gain margin chart, to a gain margin of -4 db to 8 db and a phase margin of ± 35 degrees. With only the two design variables to work with the pole placement and robustness design program was unable to place the poles and adjust the singular value level to the required value. The poles were placed at -2, -2 but the singular value minimum was still on the order of -23 db or 0.07. The pole-zero plot remained almost unchanged. It is clear that additional degrees of freedom for the pole placement and robustness design program must be opened if robustness is to be accounted for.

Case three was then run on the pole placement and robustness program by adding on additional degree of freedom. This case used the f gain as the additional design variable. A good choice as will be seen. Allowing the optimizer routine the extra freedom to adjust the additional feedback gain term an excellent design was found. The singular value minimum became 0.885 as shown in figure 6.8. Using the universal gain margin chart this corresponds to gain and phase margins of -6 db - 18 db and ±52 degrees respectively. This is a considerable improvement over the original design. The factor that changed the design was the upper diagonal feedback term which provides a cancelling factor for the cross-coupling term b 12 = 50. This can be seen by looking at the system matrix equation 6.11.

$$A_{c} = A - BF \tag{6.11}$$

where equation 6.12 gives A .

$$\frac{A}{-c} = \begin{bmatrix} -1 - f_{11} & -f_{12} - b_{12} f_{22} \\ 0 & -1 - f_{22} \end{bmatrix}$$
(6. 12)

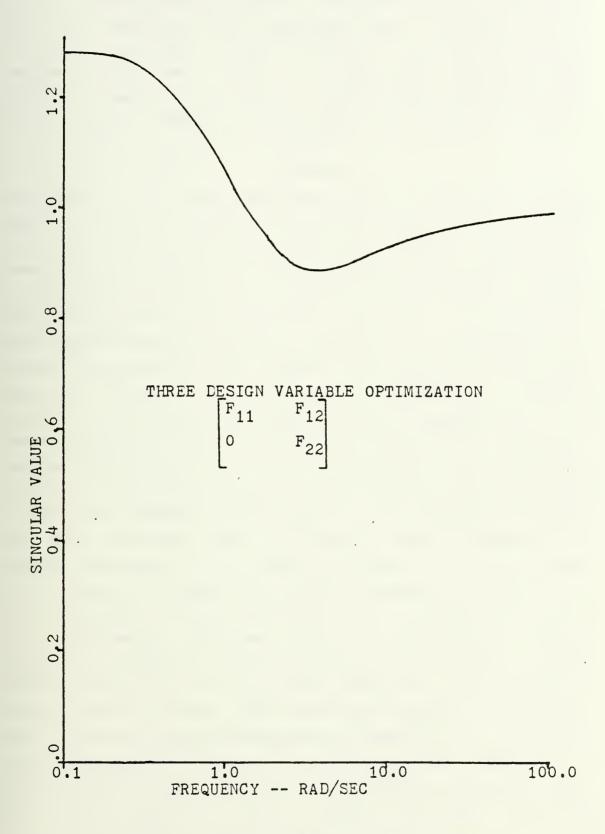

Figure 6.8 Singular Value Plot Case Three.

If the upper diagonal term of the matrix can be driven to zero the system will be decoupled into a diagonal system. To place the poles of this system at -2, -2 the diagonal feedback gains must be one. The optimizer feedback gains for this case were  $f_{ij} = 1.00006$ ,  $f_{ZZ} = 0.99998$  and, most importantly,  $f_{ij} = -51.83401$ . Using these values in the A matrix

A = -2.00006 1.83501 0.0 -1.99998

The value in the upper right position in the system matrix has been lowered considerably from the value of near 50 that appears in this position in the low singular value cases. Lowering this system gain value decreases the cross-coupling perturbation effects on the system. This can be more graphically demonstrated by figures 6.9 and 6.10. In figure 6.9 the transfer function shows a high gain of approximately 35 db and a bandwidth of 50 rad/sec. In figure 6.10 this gain has been reduced to 6.0 db with a bandwidth of almost 2 rad/sec. Two things are indicated by the figures, one, the open-loop Ecde plot of the transfer function of the crosscoupled channel can be used to indicate the robustness problem as evidenced by the high gain and bandwilth relative to the other feedback gains and, two, the mechanism used by the pole placement and robustness design procedure to recover robustness is to reduce the relative gain and associated bandwidth within the affected channel. Figures 6.11 and 6.12 which are for the input one to output one channel are approximately the same as are the Bode plots for the input two to output two channel which are not shown. These figures indicate that no problem exists in the diagonal or direct coupling terms. The pole-zero diagram for optimization run case three is included in figure 6.13. The only significant change in this plot as compared to figure 6.7 is the movement of the zero in the off diagonal pole-zero plot. The zero is seen to shift to one of the pole locations

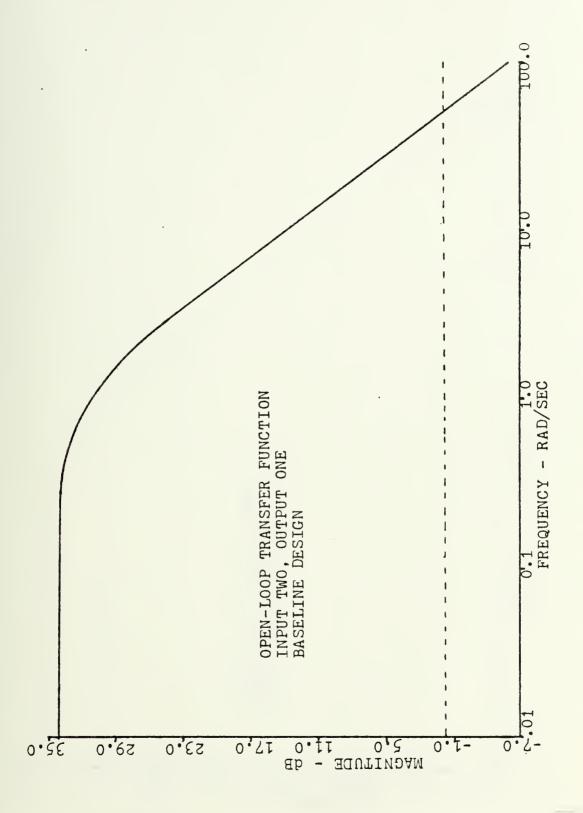

Figure 6.9 Open-loop Transfer Function 2-1 for Baseline.

Pigure 6.13 Closed-loop Pole-Zero Plot Case 3.

during the optimization. This zero shift has the effect of smoothing the frequency response curve in the vicinity of the frequency of the minimum singular value providing a more uniform gain distribution around this point. Table 1 shows comparison results for the feedback gains for several cases of this hasic problem.

The logical extension of the problem to the general case is to allow all four feedback gains to become design vari-

TABLE 1
Comparative Results Simple Problem

	Feedback Gains			
	f <sub>11</sub>	f <sub>12</sub>	f <sub>21</sub>	f <sub>22</sub>

f <sub>21</sub> variable f <sub>12</sub> =0	0.25254	0.0	-0.01071	1.52332
f <sub>21</sub> variable f <sub>12</sub> =-50	.99960	-50.0	0.00025	0.99038
All f's variable	1.11936	-60.4718	0.00280	0.75478

ables. The pole placement and robustness routine can then use full freedom in choosing all four of these feedback gains to compensate for any cross-coupling effects within the system. Based on the previous analysis the two diagonal gains would be expected to approach 1 while the upper off diagonal gain moves to -50 and the lower one moves to 0. The flexibility of the ADS program was required for the four design variable study. Several runs were made with various combinations of starting parameters for the feedback gains and optimizer routines before a good design for the case

incorporating all four feedback gains as variable was obtained. While this points out one of the limitations of optimization design routines the program was able to develop an improved design over the baseline while employing four design variables. In the design produced for this case the singular value level was placed above 0.6 for a gain margin of -4 db to 9 db and phase margin of ± 35 degrees. In this formulation the optimizer was able to place the poles and meet the design singular value level. The feedback gains produced by the optimizer were:

**1.11**936 -60.4718 0.0028 0.75478

which are approaching the analytic design gains. After obtaining the feedback gains the OPTSYS program was used to obtain the necessary data to do a closed-loop pole-zero map. This plot is shown in figure 6.14 These plots indicate a similar pole-zero location to that found in the previous three design variable problem. Again the gain in the affected channel has been reduced to compensate for the high cross-coupling perturbation within the system.

The design studies presented to this point have been based on breaking the system loop at the input as shown in figure 6.15. In multivariable theory the location of the break in the loop changes the return difference for the system and the transfer function formulation. In the figure number 1 depicts a system with an input loop break point while number 2 is an output loop break point for output return difference determination. The return difference function for the point 1 is written as I+FG while the return difference for point 2 is I+GF. The baseline system not only has low singular values of the input return difference matrix, the lowest being 0.0706, but also has low singular values for the output return difference matrix of point 2 of about the same order. To demonstrate the versatility of the

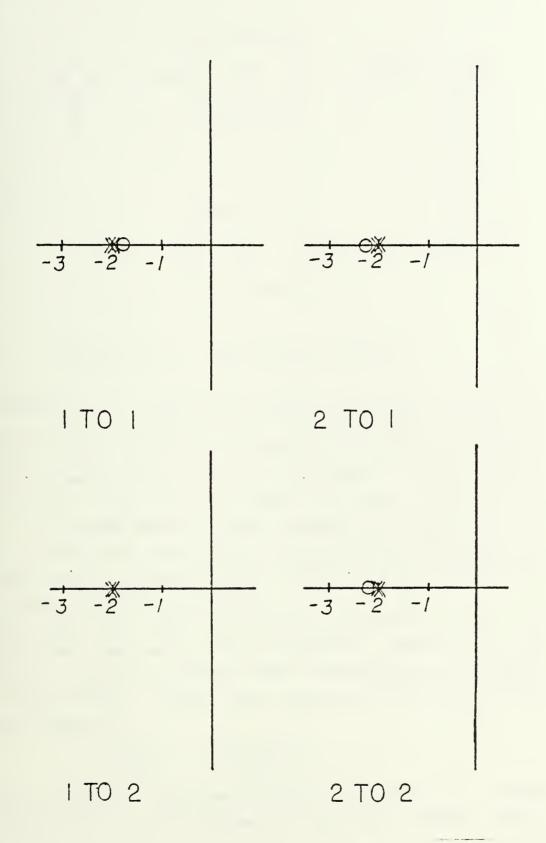

Figure 6.14 Pole-Zero Plot Simple Problem (4 Variables).

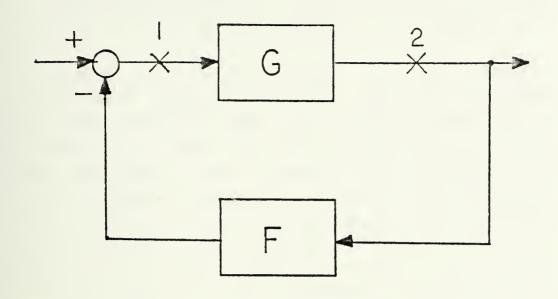

Figure 6.15 System Block Diagram.

pole placement and robustness routine a design was made in which the output singular values were specified instead of the input values. The pole placement and robustness routine produced a design with gains that provided a highly robust system on the output side with gain and phase margin of -6 db to and phase margin of ±60 degrees. The design was not robust on the input side. Thus, designing for robustness at one point in the system does not necessarily give robustness at all points within the system.

Cne final case that should be discussed is that of setting both input and output robustness criteria at the same time. Excellent results were obtained for this case. The design routine placed the poles at -1.97±.009j with feedback gains of

0.85793 -45.91757 0.00425 0.87137

The input singular values were raised to a level of 0.74984 or -4.5 db to 12 db gain margin and ±43 degrees phase

margin. The output values were raised to above 0.822 which corresponds to -5 to 15 db gain margin and ±49 degrees phase margin.

Ic summarize, it can be stated that the robustness problem for this system exists in the upper cross-coupling channel (input two, output one). The lack of robustness can be discovered in two ways. The first method is to plot the open-loop Bcde plots cf each element of the transfer matrix and lock for extremely high gains and bandwidths relative to the other transfer functions. The second method examines the singular values of the return difference matrix for magnitude. Low singular values correspond to low robustness. The role placement and robustness design routine can increase robustness by modifying feedback gains to reduce the effect of cross-coupling within the system. Observing the gain modification made by the pole placement and robustness rcutine the critical channel within the system that affects the robustness may be determined from the Bcde The pole placement and robustness routine feedback gain changes also cause zero shifts during the robustness recovery. The gain on the open loop Bode plot for the affected crcss-coupling channel is adjusted and the clcsedloop zeros, as seen on the pole-zero diagram, are shifted. This zero shift is in a direction which will combine with system poles to smooth the frequency response diagram in the vicinity of the minimum singular value.

## VII. A HELICOPTER STABILITY PROBLEM

This chapter will deal with a more practical application of the numerical optimization program. In this problem the combined pole placement, robustness design procedure will be applied to the linear lateral dynamic channels of a CH-47 helicopter. The model is a highly coupled two-input twocutput system that has been studied for its basic robustness characteristics [Ref. 16]. The usual procedure for design of highly ccupled systems is to obtain a diagonally dominant closed-loop system. This diagonal system will be stable but not robust to cross-feed parameters. Sandell, et al, produced three designs. Two cf these designs, while meeting hasic performance criteria, had poor robustness. The third design was a relatively good design. The numerical optimization technique developed in the thesis was applied to the two poor designs and shown to provide substantial improvement in robustness.

The systems were designed to satisfy specifications to step input response and stability margins as stated in military specifications. Specific design parameters for each of the three designs presented were not available. The designs were all considered to meet the performance specification criteria and stability margin requirements. It was shown that two of these designs were extremely sensitive to model errors. The classic Nyquist techniques did not predict this sensitivity. The singular value analysis did indicate sensitivity problems.

The model is that of a CH-47B helicopter lateral dynamic system in hover. The dynamic model of the system is

$$\dot{\underline{x}} = \underline{A} \underline{x} + \underline{B} \underline{u} \tag{7.1}$$

$$X = (v_p, r_p, q) \tag{7.2}$$

$$u = (\delta_{\mathbf{g}}, \delta_{\mathbf{c}}) \tag{7.3}$$

and where

$$B = \begin{bmatrix} 0.12 & 0.95 \\ 0.04 & -8.37 \\ .34 & 0.02 \\ 0 & 0 \end{bmatrix}$$

with full state available for feedback. Table 3 is a summary of parameters. The system is not open-loop stable.

Three control laws are formulated to satisfy the desired performance specifications. Equation 7.4 is the basic control law.

$$\underline{\mathbf{u}} = -\mathbf{F}_{i}\mathbf{x} + \mathbf{h}_{i} \boldsymbol{\varphi}_{e}$$

$$i = 1, 2 \text{ or } 3$$

$$(7.4)$$

where the following values of F and h were are:

$$F_{1} = \begin{bmatrix} -1.72 & -23.5 & 70.6 & 595. \\ 0.024 & -2.71 & 0.368 & -7.99 \end{bmatrix}$$

$$F_{2} = \begin{bmatrix} 0.198 & 154.0 & 18.3 & 142.0 \\ -0.01 & -1.592 & -0.189 & -1.47 \end{bmatrix}$$

$$F_{3} = \begin{bmatrix} 0 & 0 & 25.5 & 0 \\ 0 & -4 & 0 & -27 \end{bmatrix}$$

TABLE 2
CH-46 Helicopter Parameter Definitions

Variable	Units	Description		
v	ft/sec	Vehicle body y-axis earth relative velocity component		
p	rad/sec	Roll rate		
r	rad/sec	Yaw rate

δ <sub>B</sub>	in	Yaw rate rotor deflection control		
δ <sub>C</sub>	in	Roll rate rotor deflection control		

$$h_{z} = \begin{bmatrix} 597.0 \\ -7.99 \end{bmatrix}$$

$$h_{z} = \begin{bmatrix} 142.0 \\ -1.47 \end{bmatrix}$$

$$h_{s} = \begin{bmatrix} 0 \\ -27 \end{bmatrix}$$

The  $\varphi_c$  is a step input command that must track. Figure 7.1 is a diagram of the control structure for the feedback control laws. Figure 7.2 is a detailed layout of the system. All three cf the designs have negative real eigenvalues and provide stable overdamped responses. All three of the above designs meet the desired design specifications.

The loop Bode rlots, [Ref. 16], indicate all three designs to have good stability margins when considered a loop at a time. Since these designs were all full state LQ

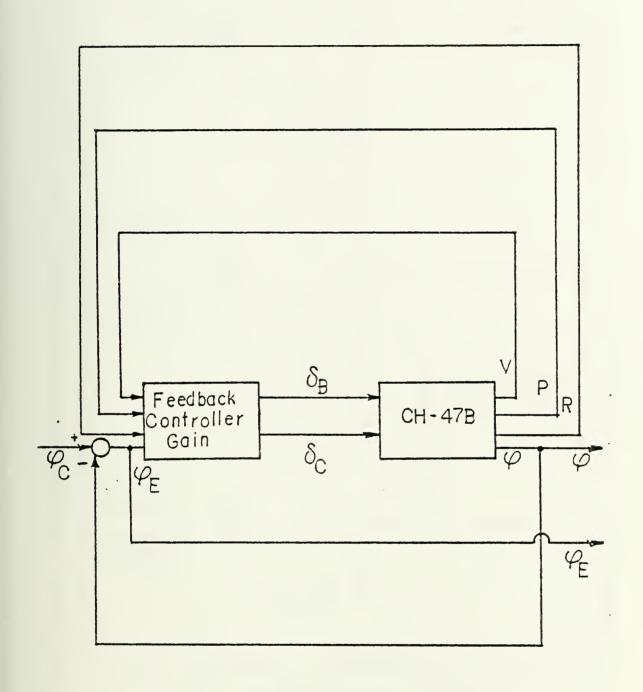

Figure 7.1 Feedback Control Structure.

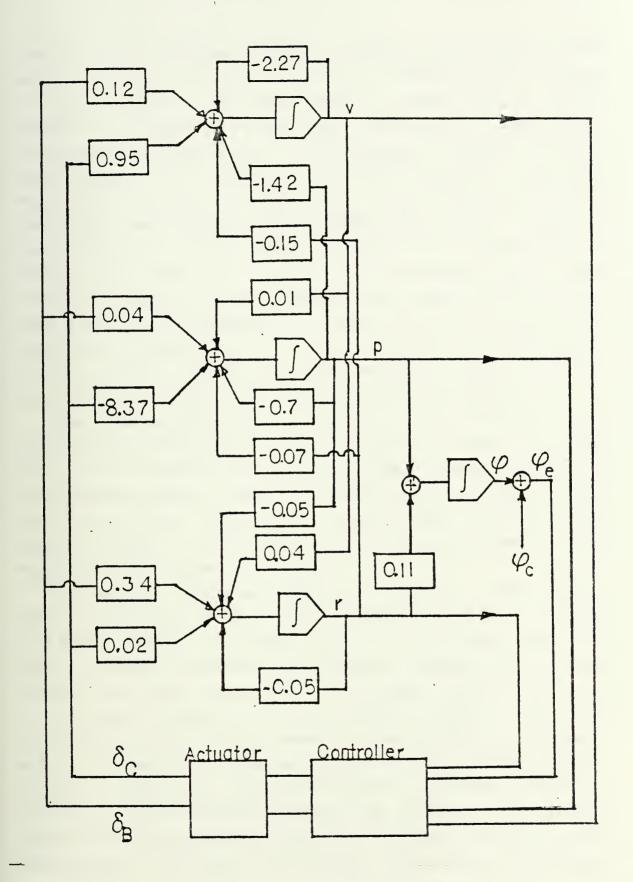

Figure 7.2 System Diagram.

designs with a diagonal control weighting matrix they should posses at least -6 db to infinite gain margin and 60 degrees of phase margin. When the singular values of the three designs are computed a robustness problem is indicated by low singular values of two of the designs. Figure 7.3 presents singular value plots of all three designs. This plot shows that designs 1 and 2 both have very low minimum singular values for the return difference matrix. Design 1 goes as low as -20 db near 10 rad/sec in frequency while design 2 is down to -34 db at frequencies up to 1000 rad/sec. Design 3 is a good design with singular values that remain above one throughout the frequency range of interest. Using the universal gain and phase diagram as discussed in Chapter 6 this equates to a gain margin of about -6 db to infinity and a phase margin of 60 degrees as expected.

The system stability in design 1 may be affected by perturbations occurring in the actuators as shown in figure 7.4. If the output axis coupling from  $\delta_c$  spills into  $\delta_B$  in the frequency range from 0.5 to 50.0 rad/sec with a magnitude of 0.12 and a phase of 60 degrees then the system can become unstable. This could be caused by nonlinear terms, worn parts, or system saturation.

The second design as shown in figure 7.5 may have a stability derivative variation between  $\delta_{\theta}$  and p. If this derivative varies from about 0.04 to -0.96 the system can become unstable. The center of gravity location, trim of the aircraft and roter coupling can all affect this derivative.

The pole placement and robustness design technique developed for this thesis research was applied to designs 1 and 2 to obtain an improved robustness for these designs. Design 1 will be considered first. In this design a cross-feed perturbation through the actuator can produce instability as indicated by the low singular values at lower frequencies. To study this problem with the pole placement

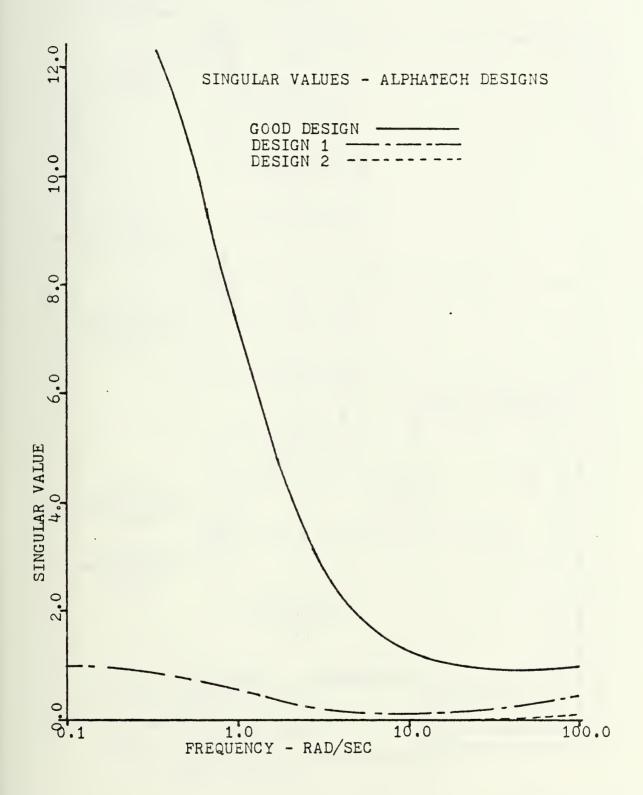

Figure 7.3 Alphatech Design Singular Value Plots.

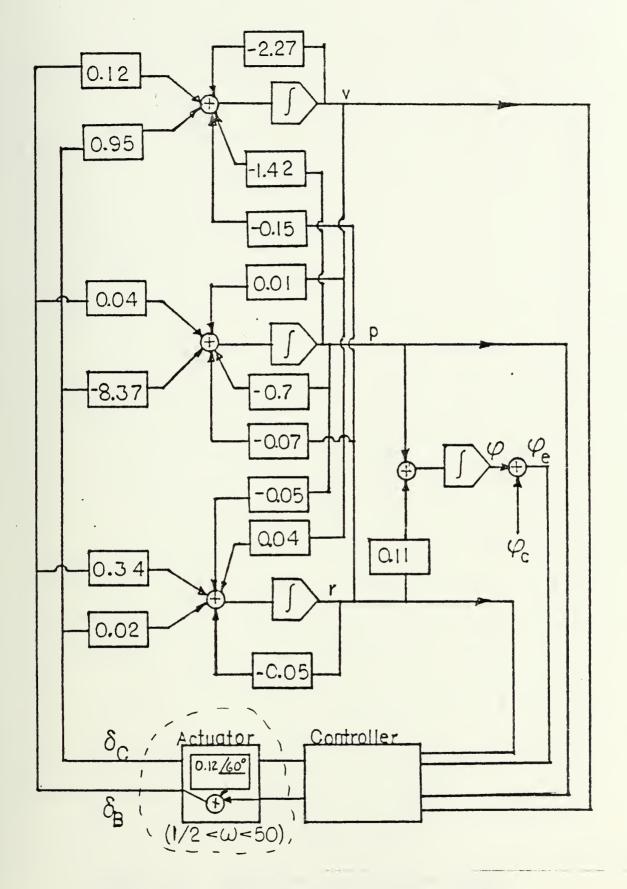

Figure 7.4 Design One Perturbation Input.

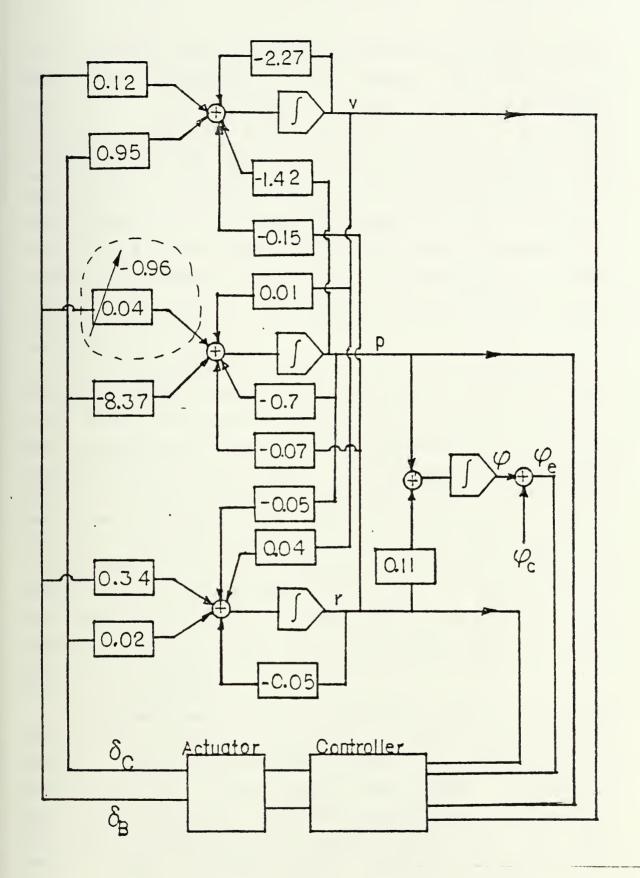

Figure 7.5 Design Two Perturbation Input.

and robustness design method it is assumed that the eigenvalues (pole locations) of the system as developed in [Ref. 16]. are the required poles for the performance criteria. Once the pole locations are set, robustness criteria must be selected. From the universal gain and phase margin curve discussed earlier two choices of singular value levels were made for this problem. The first singular value level chosen was 0.6. This corresponds to a gain margin of -4.0 db to 8 db and a phase margin of about 35 degrees. The second value chosen was 1.0. With corresponding gain margin of -6 db to and a phase margin of 60 degrees which are the characteristics of a LQ regulator design with diagonal weighting matrices.

For singular value level 0.6 the pole placement and robustness design routine places the poles as shown in table 2 The slight differences in these pole locations appear to have insignificant effect on the performance as shown in the response curves of the system. The feedback gain adjustment moves the minimum singular value from about 0.11 with very poor phase and gain margins to a level of 0.66. This is above the desired values of gain and phase. The improvement in robustness came from modifying the feedback gains in channel  $\delta_{\mathcal{B}}$ . By greatly reducing the gains in channel  $\delta_{\mathcal{B}}$  the optimizer minimizes the influence of the cross-coupling from channel  $\delta_{\mathcal{C}}$ . In this way a much larger spill over of channel  $\delta_{\mathcal{C}}$  may be tolerated through the actuator before the system will become unstable.

The primary mechanism of robustness improvement in this problem was a reduction in the gain levels of the affected channel. The feedback gains presented in table 4 show the modification of these gains from those utilized in [Ref. 16]. While all the gains are modified the f<sub>14</sub> gain undergoes a significantly larger change than the other design 1 case 1 feedback gains. Looking at the open-loop

TABLE 3
Design One Pole Placement

Pole	Desired Location	Actual Location
1	-24.7977	-24.7893
2	-11.3635	-12.0083

4	- 2.1005	- 2.1181

transfer functions of this optimized problem and comparing them with a non-optimized set of transfer functions for  $\delta s$  to as shown in figure 7.6 and 7.7 show very little change in the system gain, both are around 42.0 db, and a bandwidth of about 20 rad/sec. There is a significant change in the phase diagram which is caused by the zero location shift.

The transfer function for  $\mathcal{S}_{\mathcal{C}}$  to  $\mathcal{S}_{\mathcal{C}}$  depicted a gain increase of about 3 db for the optimized design while the phase remained similar for both transfer functions. In transfer function  $\mathcal{S}_{\mathcal{C}}$  to  $\mathcal{S}_{\mathcal{B}}$  some important aspects of the problem are observed. The Bode diagram of the open-loop transfer function of  $\mathcal{S}_{\mathcal{C}}$  to  $\mathcal{S}_{\mathcal{B}}$  clearly indicates the cross-coupling problems and the pole placement and robustness design routine's mechanism of optimizing the system gains to increase robustness. The gain is reduced from 93 db to about 78 db and the bandwidth is reduced from above

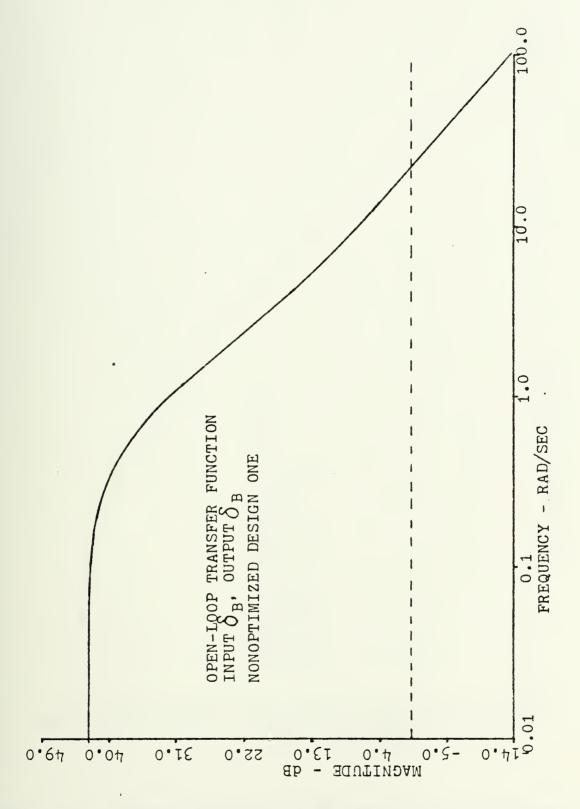

Figure 7.6 Transfer Function  $\delta_B - \delta_B$  Design One, Nonoptimized.

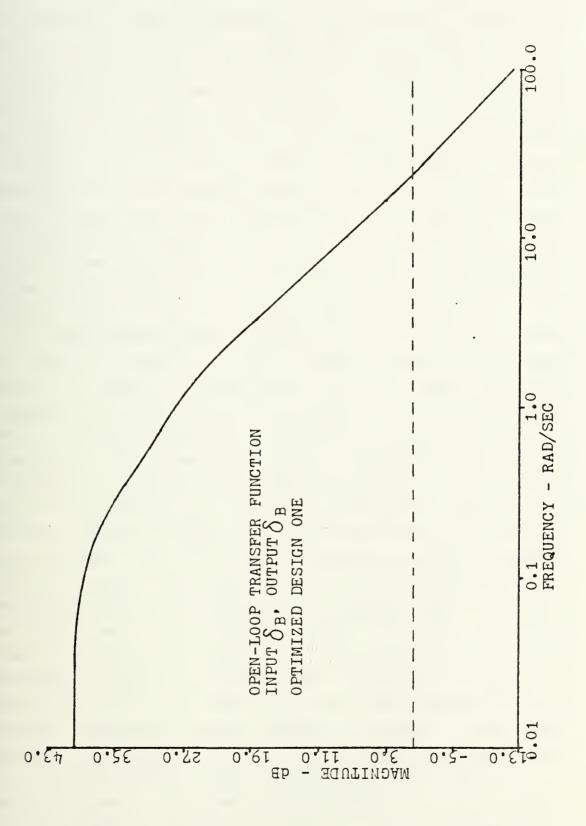

Figure 7.7 Transfer Function  $\delta_8$ - $\delta_8$  Design One . Optimized.

100 rad/sec to about 30 rad/sec. The reduction of bandwidth and gain in the loop & to & yields an increased tolerance to perturbation. The transfer function for & to & is shown in figures 7.8 and 7.9. In the transfer functions for & to & the bandwidth is slightly increased from 0.6 to 0.8 rad/sec and the gain actually increased from 9 db to 14 db. The big change in the overall system, however, is in the transfer function from & to & . This is the channel that the destabilizing perturbation enters and by greatly reducing the gain and bandwidth in this channel through a change in feedback gain, the optimizer routine has brought the entire system gains to more balanced conditions and recovered a highly robust design.

The gain changes associated with the robustness improvement cause the zeros of the various closed-loop pole-zero diagram to move. A comparison of the eight pole-zero diagrams is shown in figures 7.10 to 7.13. The significant feature of these pcle-zero diagrams is the shift of the zeros of the optimized design in a direction that attempts to equalize or balance the frequency response for frequencies in the vicinity of the minimum singular values. pole-zero diagram of Se to v will be discussed as an example of this effect. In 7.10 the nonoptimized zeros are located about -2 ± 4.5j and -19.8. When the pole placement robustness routine has completed the feedback gain mcdification these zeros have shifted near -11 and -6±3j. effect of these zero shifts is to combine with the pcle locations to equalize the frequency response as depicted in figures 7.14 and 7.15. Zero shifts for the remainder of the transfer functions provide similar results in the other channels. By moving toward the frequencies associated with minimum singular values the zeros have balanced the overall frequency response of the system in each channel. While the channel gain modification is the primary mechanism

for robustness recovery the zero shift associated with the feedback gain changes is directly related to the overall frequency response of the system.

In design 1 case 2 the minimum singular value level was increased from 0.6 to 1.0. The pole placement and robustness design procedure also gave a better design for case 2

TABLE 4
Helicopter Problem Feedback Gains

CESIGN	GAIN VALUES $\begin{bmatrix} f_{11} & f_{12} & f_{13} & f_{14} \\ f_{21}^{11} & f_{22}^{12} & f_{23}^{23} & f_{24}^{24} \end{bmatrix}$

by modifying the feedback gains as shown in table 4. The change in the transfer functions for  $\mathcal{S}_{\mathcal{L}}$  to  $\mathcal{S}_{\mathcal{B}}$  (figure 7.16 and 7.17) is similar to the change seen in figures 7.8 and 7.9. The gain was reduced from above 90 db to about 75 db and the bandwidth cut from above 100 rad/sec to about 25 rad/sec. The added requirement of increased robustness did not result in a significant change in performance. [Ref. 16].

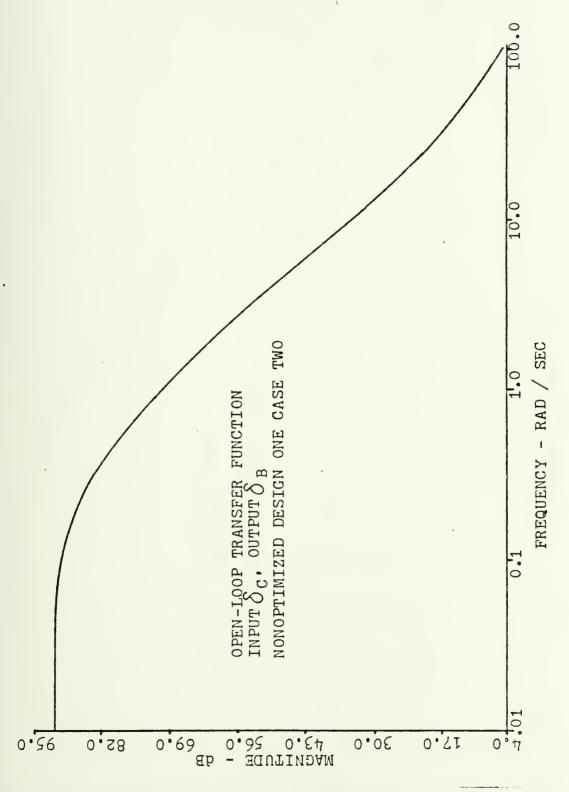

Figure 7.16 Transfer Function  $\delta_c - \delta_B$  Design 1 Case2, Nonopt..

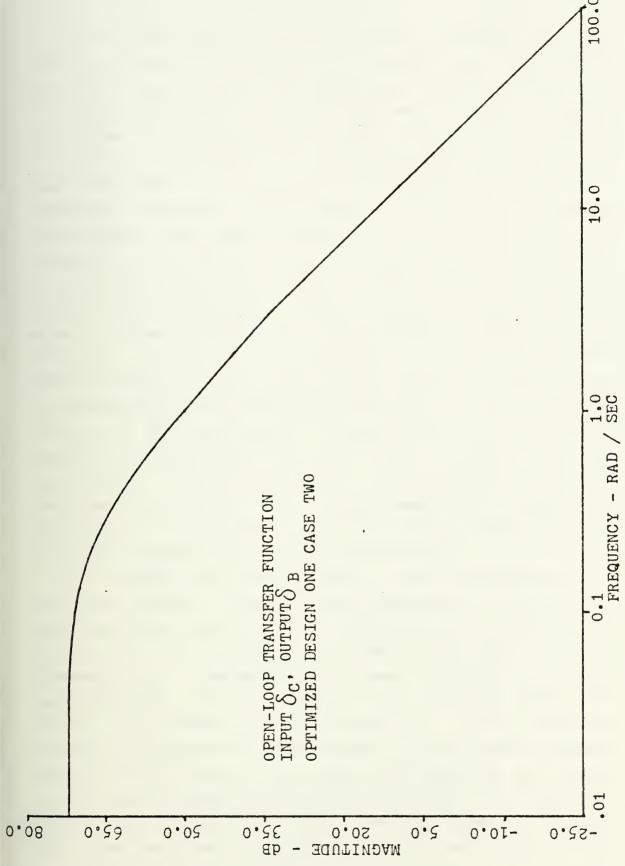

Figure 7.17 Transfer Function  $\delta_c$  -  $\delta_B$  Design 1 Case 2, Opt.

Design two which is the design that is subject to parameter uncertainty in the &s to p channel was also studied using the pole placement and robustness design routine. this design the singular values were very low until frequencies above 100 rad/sec were reached. To improve the design it was assumed that the pole locations that corresponded to [Ref. 16] were the required pole locations and that a robustness singular value level of 0.6 would provide adequate gain and phase margin for the design. The pole placement and robustness routine adjusted the gains in this problem until a minimum singular value of 0.6 was obtained. During this adjustment the gains in channel  $\delta s$  were considerably reduced to offset the cross-coupling between the two Again, in this design as before the channel cross-coupling between & and & shows a marked change in bandwidth and gair from above 100 to 35 rad/sec and about 78 db to 22 db respectively. Figures 7.18 and 7.19 show the transfer function plcts for this term. Figure 7.20 shows the singular value improvement. In figure 7.21 the time response is plotted. As can be seen in the plot the improvement in robustness for this problem results in very sluggish response and degraded performance.

To summarize for this problem, a given performance level has been chosen in terms of pole locations. The level of robustness has been set for a desired gain and phase margin based on the universal gain and phase margin curve. The pole placement and robustness routine has been able to improve the robustness level by changing the feedback gains that affect the channel & cross-coupling. This robustness recovery is affected by modification of the system feedback gains in such a manner that cross coupling gains are reduced so that small cross-coupling perturbations do not drive the system into instability. The open-loop transfer function plots have been used to indicate how this mechanism operates

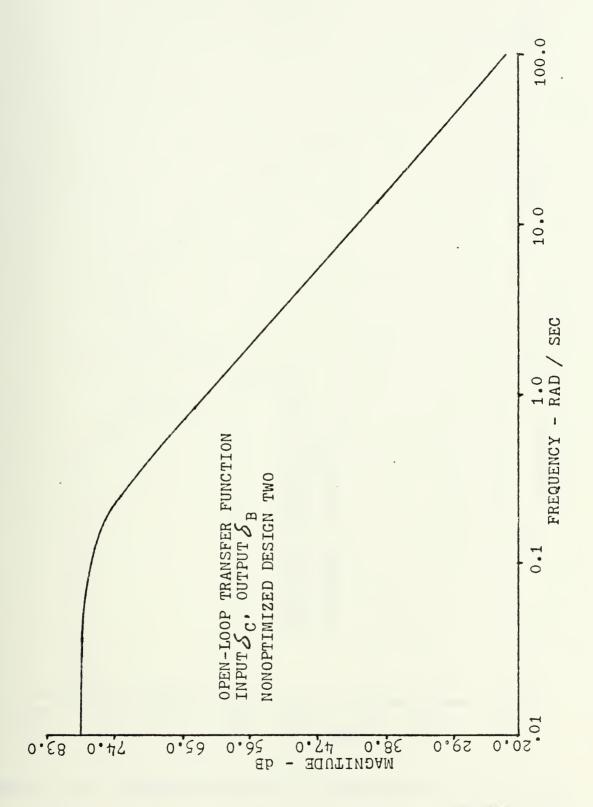

Figure 7.18 Transfer Function  $\delta_c$  -  $\delta_8$  Design Two, Nonopt...

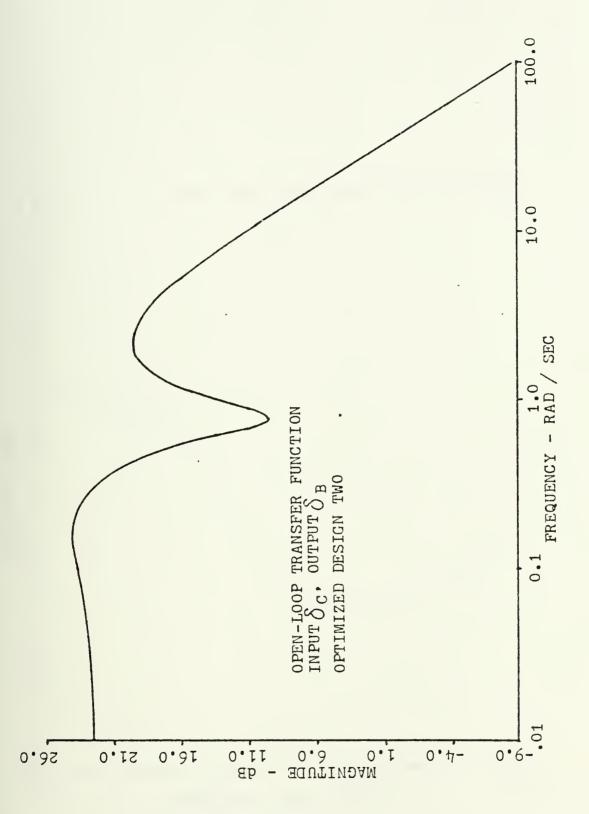

Figure 7.19 Transfer Function  $\delta_c$  -  $\delta_B$  Design Two, Optimized.

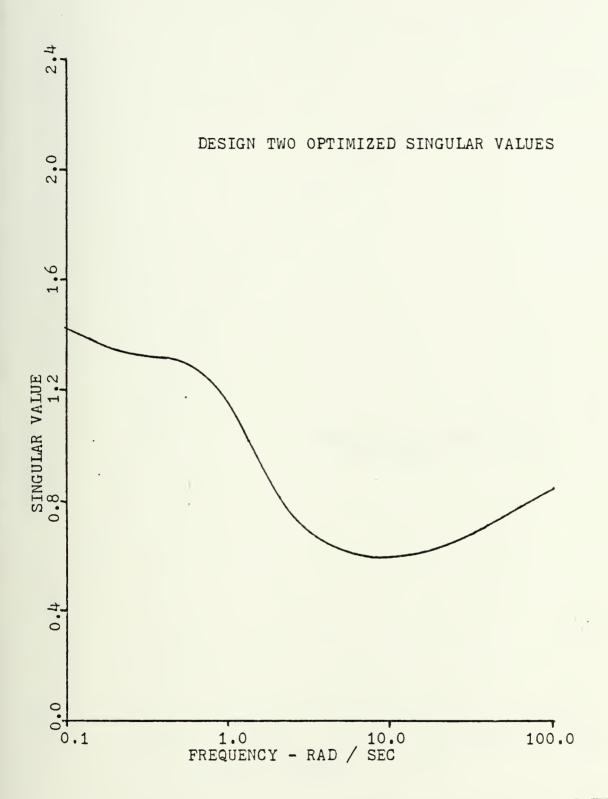

Figure 7.20 Singular Value Plot Design Two.

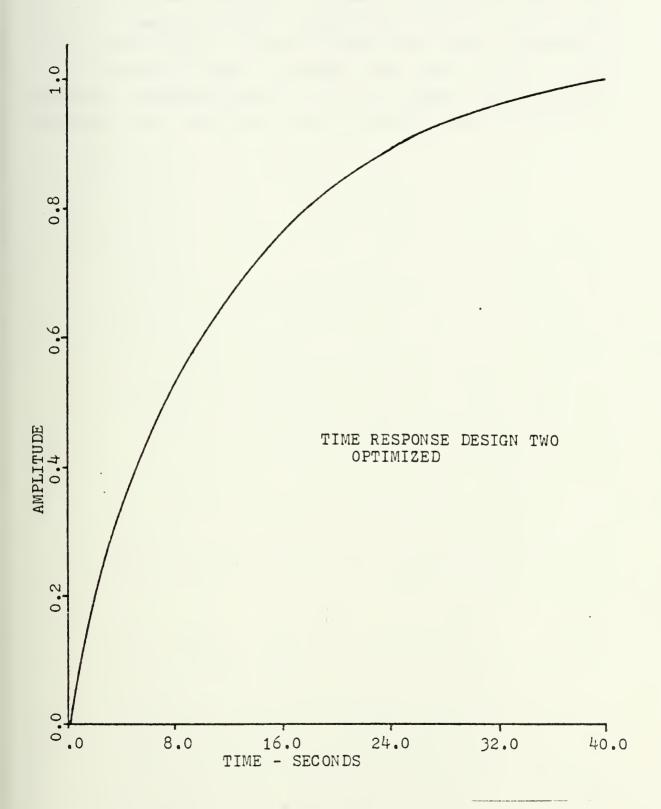

Figure 7.21 Time Response Design Two.

and have been shown to be an alternative indicator of channels that may be affected by cross-feed perturbations. The pole-zero diagrams of the closed-loop transfer functions of the transfer matrix further indicate that zero movement is in a direction that equalizes the gain level of the frequency response curves in the vicinity of the lowest singular values providing a more balanced system response.

## VIII. SIMPLE OBSERVER

The pole placement and robustness design procedure can also be used for robustness recovery in observer design.

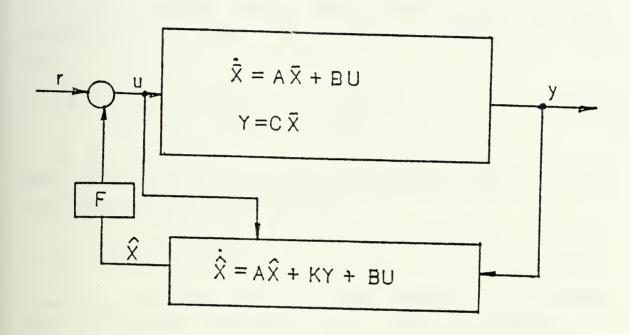

Figure 8.1 Simple Observer.

Given an observer as represented in figure 8.1 it has been shown that the system differential equation may be written as equation 8.1

$$\dot{\hat{x}} = \begin{bmatrix} A & -BF \\ KC & A_C - BF \end{bmatrix} \begin{bmatrix} \hat{x} \\ \hat{x} \end{bmatrix} + \begin{bmatrix} B \\ B \end{bmatrix} T$$

$$A_C = A - KC$$
(8.1)

where x is the state and x is the observer variable, and the solution may be separated to independent solutions for the feedback gains and the observer gains. This separation allows the use of the feedback gains to set the pole

locations and then a second optimization run with set feed-back gains so that the observer gains may be computed to adjust the system robustness level. The observer pole location could also be placed using the observer gains, K. In the currently implementation of the pole placement and robustness design routine the observer poles are simply restricted to areas of the left half plane.

In this chapter a simple stable observer system will be analyzed based on [Ref. 17]. Given the system, equation 8.2,

$$\dot{\mathbf{x}} = \begin{bmatrix} 0 & 1 \\ -3 & -4 \end{bmatrix} \mathbf{x} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} \mathbf{u} + \begin{bmatrix} 35 \\ -61 \end{bmatrix} \mathbf{y}$$

$$\mathbf{y} = \begin{bmatrix} 2 & 1 \end{bmatrix} \mathbf{x} + \eta$$
(8.2)

where  $E(\tau) = E(\tau) = 0$  and  $E(\tau(t), \tau(\tau)) = E(\tau(t), \tau(\tau)) = S(t-\tau)$  with the feedback law of equation 8.3

$$u = -(50 \ 10) x + 50r$$
 (8.3)

An analysis has been done to compare results of the numerical optimization procedure with results presented in [Ref. 17]. The results for an optimal regulator design using quadratic cost criteria as stated in equation 8.4 are given in table 5

$$J = \int (x^T H^T H x + u^2) dt$$
 (8.4)

with  $H = 4\sqrt{5} (\sqrt{35} 1)$ 

Figure 8.2 shows a Nyguist plot of the full state regulator, the optimal filter and a fast filter. The full state design had poles at  $s=-7.0\pm j$  2.0 and feedback gains of 50 and 10. The optimal filter as shown in table 5 had poles of  $-7.0\pm j$  2.0 with gain and phase margins of -6.75 db and  $\pm 15$  degrees. The optimum filter gains were 30 and -50. Using a faster

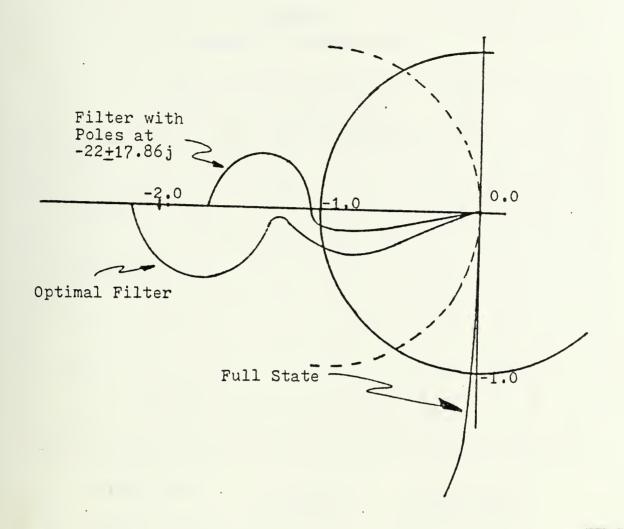

Figure 8.2 Nyquist Plot.

margins are on the order of -.98 while the phase margin is less than 10 degrees. The bandwidth also increased from 12 to 40 rad/sec. A recovery procedure based on a modification to the process noise matrix [Ref. 17] may be applied to the problem. This procedure can recover a large amount of the robustness that was lost with the observer addition. Figure 8.3 shows data obtained for several trials of the fictitious noise procedure. The gain, phase margin and other parameters may be found in table 5.

The singular values of the state feedback and optimal cbserver systems were computed for comparison with results produced using the pole placement and robustness design recovery procedure. Figure 8.4 indicates a loss in robustness represented by the observer singular values. Iower singular values are less robust. For this single-input single-output observer the Nyquist diagram will be used to define gain and phase margins. Since a singular value of 1.0 is indicative of a linear quadratic level of gain and phase margin, i.e. GM=-6 db, and PM=±60 degrees, this was chosen

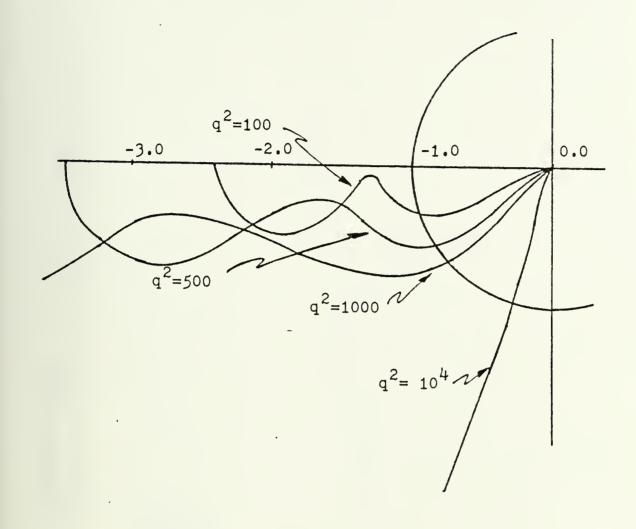

Figure 8.3 Nyquist Plot for Robustness Recovery.

as the design level. The pole placement and robustness routine was used to recover robustness while setting the pole placement at the state feedback pole locations of -7±j2. The minimum input singular value level was set at 1.0. The pole placement and robustness routine was also set to place the observer poles anywhere between -100 and -2 that would provide robust design. The plant poles were placed at -7.05 ±j 1.82. The feedback gains for this run

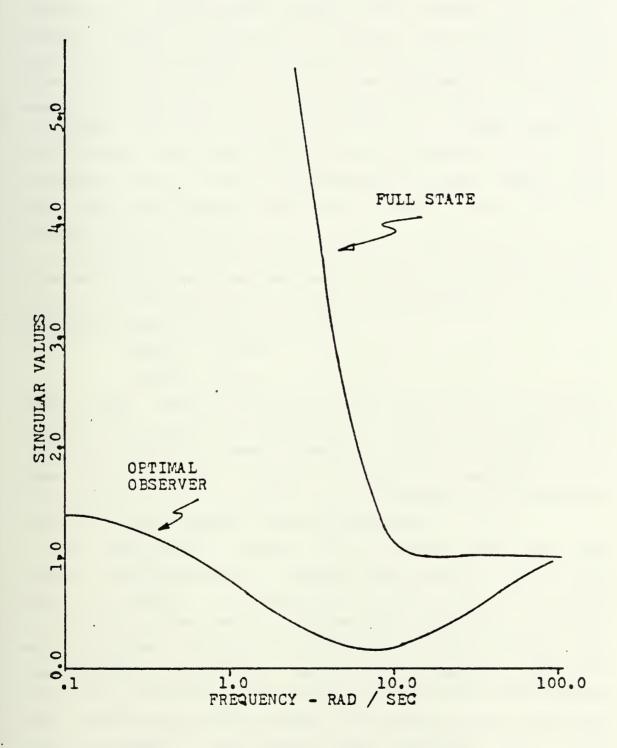

Figure 8.4 Singular Values of Observer System.

were 50 and 10.09. The optimizer output produced a filter with a gains of 1.00018 and -2.02742. The observer pole locations were -1.99 ± j .001, very near the plant zero location. A significant change was produced in singular values. Figure 8.5 shows all singular value curves plotted together. The optimizer solution for this problem is well above the optimal filter curve at low frequency. Figure 8.6 shows the Nyquist plot of the optimizer developed design. The system has a gain margin of -6 db and a phase margin of 117 degrees. The most significant differences between the two designs being that the observer poles are close to the plant zero locations and the filter gains are much lower for the optimizer solution.

Using the OPTSYS program with the pole placement and robustness routine computed gains as the design parameters the data for the observer filter was computed. The error covariance matrix was found to be

306.5 -456.5 -456.5 700.1

These values compare favorably with the trends established in table 5. The last comparison of the pole placement and robustness design recovery procedure was an analysis of the time response curves. Figure 8.7 shows the comparison plot. The design obtained using the pole placement and robustness routine did not degrade system performance.

Cne additional analysis was conducted that set the desired design parameters slightly differently. In this run the pole placement and robustness routine was set to place the observer poles between -10 and -100. The pole placement and robustness routine was unable to totally satisfy this requirement. It violated one of the constraints and moved the larger observer pole to -2.25 which is near the optimum pole location and also the high q<sup>2</sup> values of the fictitious noise procedure. The smaller pole was moved out to -70.8

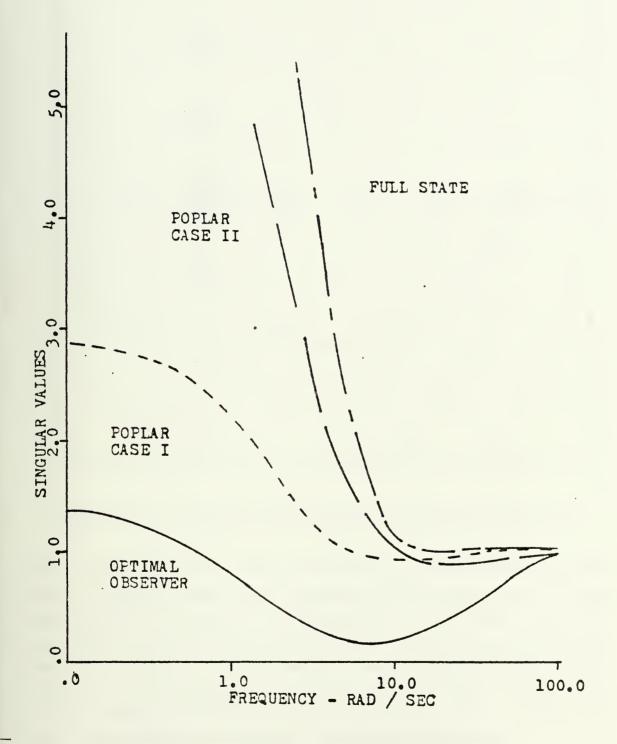

Figure 8.5 Singular Value Comparison Plot.

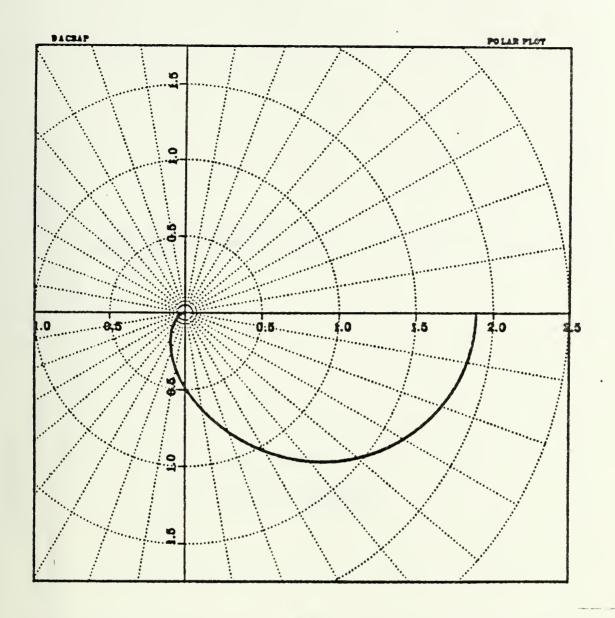

Figure 8.6 Nyquist for Computed Robustness Recovery.

which corresponds to the same level of pole movement found when q² teccmes large. The singular value levels were raised significantly as shown in figure 8.5. The state and error covariance matrices were of the same order as the matrices found in table 5. This design has a phase margin of 58 degrees. The gain margin was about -19 db. Even though some of the constraint conditions on the design were not met the design demonstrates excellent robustness recovery.

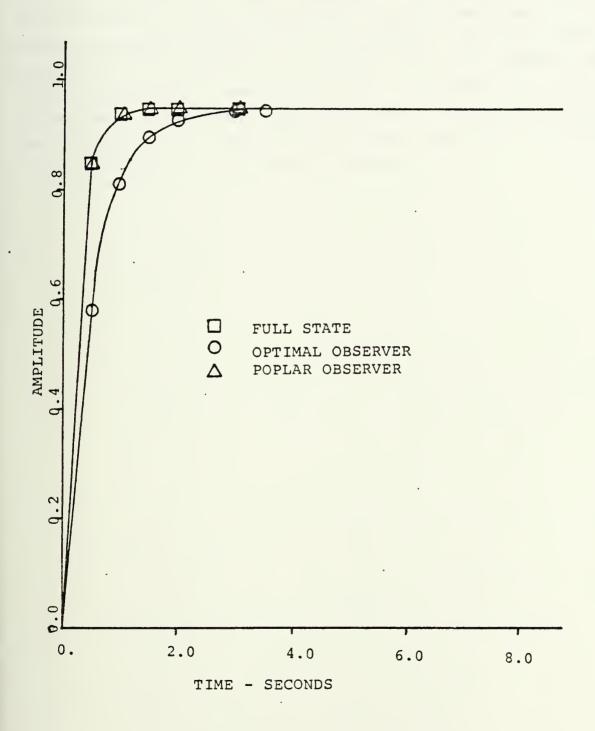

Figure 8.7 Time Response Plot for Simple Observer.

The pcle placement and robustness design routine has produced a robust design for this observer based system. This design is obtained by using a numerical optimization to directly manipulate the feedback and filter gains. Modification of the IQ functional equation as done in the fictitious noise procedure is not required. The pole placement and robustness routine solution for this problem has lower gains than those found using the fictitious noise adjustment. The routine provides a good, direct methodology for selecting the feedback and filter gains for a robust observer design with excellent performance.

## IX. ROBUST OBSERVER DESIGN

This chapter will be devoted to a short discussion of the robustness recovery of a fourth order observer based controller. The problem is a helicopter problem, [Ref. 6]. In this case the helicopter model is that of the longitudinal control loop of a CH-47. The nominal model is taken to be the system of equations 9.1 and 9.2 for an aircraft speed of forty knots.

$$\dot{\underline{x}} = \begin{bmatrix}
-0.02 & 0.005 & 2.4 & -32. \\
-0.14 & 0.44 & -1.3 & -30. \\
0. & 0.018 & -1.6 & 1.2 \\
0. & 0. & 1. & 0.
\end{bmatrix} \underbrace{\underline{x}} + \begin{bmatrix}
0.14 & -.12 \\
.36 & -8.6 \\
.35 & .009 \\
0. & 0.
\end{bmatrix} \underbrace{\underline{y}} = \begin{bmatrix}
0.100 \\
0.057.3
\end{bmatrix} \underbrace{\underline{x}}$$
(9.2)

In this problem the controller is formulated as in figure 9.1 which leads to an open-loop transfer function of the form of equation 9.3

$$K(s)G(s) = F(sI-A+BF+KC)^{-1}KC(sI-A)^{-1}B$$
 (9.3)

The prolement and robustness recovery procedure was applied to this problem.

First, the standard full state feedback design was carried out using the Naval Postgraduate version of OPTSYS. This design produced excellent singular value output for the return difference as shown in figure 9.2. The lowest singular value being essentially 1, corresponding to a LQ design with -6 db to a gain margin and 60 degrees of phase margin. The time response of the system was good as shown in

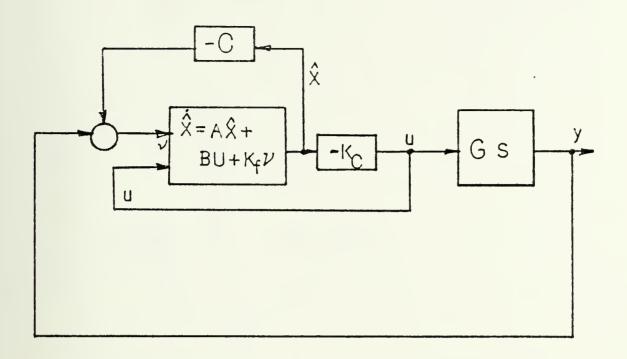

Figure 9.1 Observer Based Controller.

figure 9.3, reaching steady-state in about four seconds with only a slight overshoot. Since the characteristics for this system are acceptable no further design iteration carried out. The full state feedback became the baseline design. Assuming that full state feedback was not available and only two measurements could be produced an observer was developed to control the two measured outputs, velocity and pitch attitude. Using the measurement matrix of equation 9.2, OPTSYS was used to develop an optimal chserver system for this problem. The singular values of the return difference matrix and the time response were plotted comparison to the full state design. These are shown in figures 9.2 and 9.3 respectively. Note that the singular value of the return difference matrix is as low as 0.16 at 4 rad/sec. This equates to a gain margin of -1 db to 1 db and less than 10 degrees phase margin. The time response is

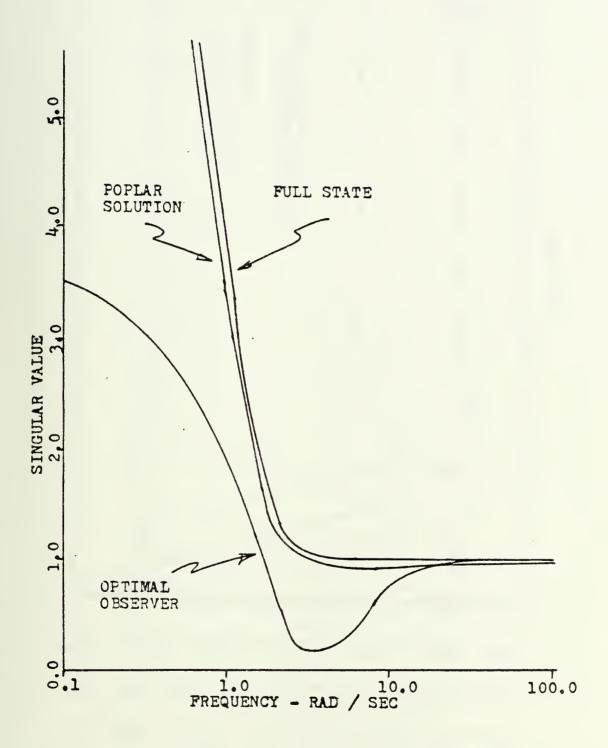

Figure 9.2 Singular Value Plot of Observer Results.

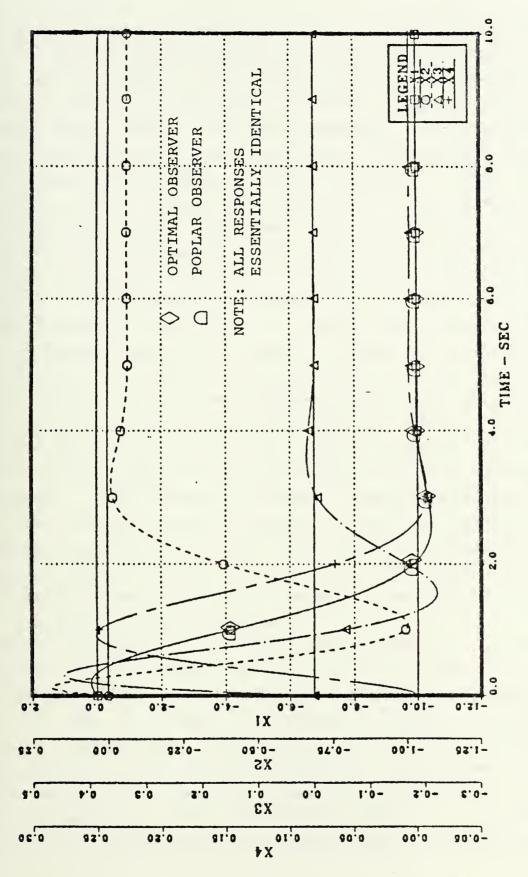

Figure 9.3 Time Response for Observer System.

plotted in figure 9.3. The steady-state was reached for the velocity after a slight overshoot in about four seconds.

As the final step in the analysis the pole placement and robustness routine was employed to recover robustness of the observer based system. The pole placement and robustness routine was first used to set the poles at approximately the same location as the roles of the LQ regulator. These were assum€d to be the desired pole locations. The pole placement and robustness routine was then used to vary the filter gains, K, until the desired level of robustness was reached. The desired singular value level chosen was 1.0 which corresponds tc -6 db to ∞ db gain margin and 60 degrees of phase margin. Figure 9.2 shows that the pole placement and robustness procedure failed to totally recover the robustness level to 1.0. The minimum singular value reached was only 0.936. This singular value equates to a gain margin of -5.0 db to and a phase margin of 55 degrees. While this is slightly less than the design objective, it is far superior to the optimal observer design discussed in the previous paragraphs. This recovery was made by making an optimization run, finding the filter gains with near zero values and freezing these values at zero. This reduced the number of design variables the pole placement and robustness routine was required to manipulate in a second optimization run and gave a higher robustness solution.

This analysis and the second order observer analysis presented earlier clearly indicate that it is possible to use the pole placement and robustness procedure and separation principle to develop a robustness recovery procedure. The pole placement and robustness routine provides robustness recovery by direct modification of the feedback and filter gains. This procedure requires no modification to LQ cost functionals or other parameters as done in the fictitious noise adjustment method commonly used for robustness

recovery. By providing direct gain adjustment the pole placement and robustness procedure results in a practical design with relatively low observer gains and good performance. The procedure is simple and straight forward with the only difficulty being a requirement to sometimes modify initial starting values or optimizer codes to force the solution toward the desired point.

## X. CONCLUSIONS

An effective method of robustness multivariable control design utilizing a numerical optimization based algorithm has been developed. The pole placement and robustness design routine coupled with the Automated Design Synthesis program provides the designer an excellent tool with which to attack the robust design problem.

The pole placement and robustness design routine has demonstrated the capability of providing designs that solve the problems caused by cross-coupling perturbations which reduce robustness in multivariable systems. This design improvement is accomplished by modifying the system feedback gains in such a manner that the gain in channels that are affected by cross-coupling perturbations is equalized with other system gains to reduce this cross-coupling effect. The gain changes are accompanied by zero shifts which also influence the gain distribution and frequency response of the system.

Perturbation problems in multivariable systems have been shown to be detectable by singular value analysis and by using the Bode magnitude diagram of the open-loop transfer functions of the system. In the open loop transfer function large differentials in Bode gains and bandwidths are indicative of problem areas for cross-coupling perturbations. Robustness is obtained by the pole placement and robustness design program by modifying those gains and bandwidths associated with the cross-coupling perturbations thus reducing the amount of energy coupled from the perturbation into other channels. An associated zero shift has been observed when these gain modifications take place. This zero shift is in the direction of poles that are located in the vicinity

of the frequency of the minimum singular value and tends to equalize the frequency response curve gains in this region.

The use of numerical optimization to recover robustness in observer based designs was demonstrated. The pole placement and robustness routine was applied to problems previously solved using the fictitious noise procedure for robustness recovery. The direct manipulation of feedback and filter gains by the pole placement and robustness routine provided a highly robust design with relatively low filter gains. The problem of robustness recovery in filter-chserver designs has been solved in a straight forward and highly practical manner.
